ORIGINAL ARTICLES.

THE MANAGEMENT OF PNEUMONIA PATIENTS.[1]

BY SIMON BARUCH, M.D.,
OF NEW YORK.

MY chief reason for bringing so trite a subject before you is that the fatality of pneumonia and the frequency of the discussion of its treatment indicate that it is very far from being settled in the minds of the profession. Another reason is a desire to summarize a personal experience extending over one-third of a century in city and country, private and hospital practice, and which represents a therapeutic evolution, a consideration of which may contribute an humble stone to that therapeutic structure which can be reared only by the aggregation of individual observations. It is hoped that the discussion of this subject to-night may furnish some clue to a better management of patients suffering from this very prevalent and fatal malady. The most effective therapeusis may be evolved only from the most thorough comprehension of the nature of disease. Whether stumbling upon it accidentally, as in the case of quinin for malarial diseases, or by a gradual evolution, as in the Brand bath for typhoid fever, or by a process of reasoning, as in the thyroid-gland treatment for myxedema, our therapeutic achievements are in proportion to our mastery of the nature of the disease.

The history of pneumonia illustrates this idea. I will not weary you with the recital of its historical stages, but confine myself to personal observations. The teaching of the schools and text-books in 1859–'62, and the practice in the military hospitals in which I served as interne, were clearly antiphlogistic, because the conception of lobar pneumonia at that time was a pure inflammation of the lung, whose tendency was to destroy life by apnea (Watson). Delirium, pyrexia, and other threatening manifestations were regarded as "direct evidence that the pectoral mischief is telling through the circulation of venous blood through the brain." It was but a legitimate deduction from this view that the chief agents to bring about recovery were the so-called antiphlogistics, by which it was hoped to throttle the local disease. It would be a bootless task to review the contending opinions prevailing before and at the time mentioned. Long before this period Dietl of Vienna had learned from the homeopaths (who were genuine Hahnemannians, and not the mongrel breed met with to-day) that pneumonia is a self-limited disease, tending to terminate favorably if the patient's vital forces be not despoiled by blood-letting, mercurials, and starvation.

Although he combated the prevailing "hematomania" with energy, he failed to make any permanent impression. In the first decennium of my active practice, Hughes Bennet and Austin Flint labored to inculcate similar doctrines. Their efforts were more successful, because the medical profession was beginning to emancipate itself from the thraldom into which that bloodthirsty monster phlogosis had cast them. In Vienna, a therapeutic nihilism attained ascendency, which, though not as fatal, did not fill the full measure of the physician's duty. Then came the quinin, aconite, and digitalis, and, later, the antipyretic era, from which the profession has not yet quite emancipated itself.

We stand to-day on the threshold of a view of croupous pneumonia which will contribute more to the saving of lives than all the doctrines and remedies suggested since the days of Hippocrates. The student is no longer taught, as I was taught, that the pneumonia patient dies from apnea. Heart failure is the specter that now stands at the bedside of the patient in this and, for that matter, in most other acute diseases. But we are, fortunately, not lapsing into the Brunonian theory of asthenia, which demanded enormous quantities of alcoholic and other stimulants. To-day it is an almost universal axiom in the therapeutics of croupous pneumonia to prevent and combat heart failure. The view that *this is an infectious disease, whose chief recognizable lesion is in the lungs, but whose lethal tendency is in the overwhelming of systemic force and vigor*, is obtaining more and more recognition.

I would go further than this, even. Careful clinical observation and a judicious sifting of the testimony of reliable practitioners have brought us to the belief that croupous pneumonia is no more a lung disease than is typhoid fever a bowel disease. Whenever this doctrine shall receive universal acceptance, we will cease to *treat the disease*, and we shall be prepared for a more effective management of patients suffering from it.

It may be said that this idea is obtaining adherents in certain quarters. All of our recent text-books insist upon maintaining the patient's vital powers as the main indication. That great American clinician, Austin Flint, read a paper before the State Medical Society in 1877, on "Pneumonic Fever," in which he referred to the analogy to typhoid fever. My interest being aroused, I discovered that, 200 years ago, Huxham had insisted upon the infectious character of pneumonia. Thus history has repeated itself in this as in other diseases, *before* the microorganisms assigned to them had been discovered.

---

[1] Read before the New York Academy of Medicine, December 3, 1896.

As to *etiology:* The present state of our knowledge may be briefly stated to be, that while cold may be a predisposing factor which diminishes the patient's resisting power, the Sternberg-Fraenkel diplococcus is an important factor in the production of croupous pneumonia, because it is present in about seventy-five per cent. of cases, although in some cases there are doubtless other organisms present. Sternberg and others have found the diplococcus in the mouths of healthy persons. Its mode of entrance into the lung and its pathogenic course are not yet clearly determined; its aspiration from the mouth seems to be claimed by most observers. The presence of some constitutional depression is a potent etiological factor. Age is a predisposing and exempting factor, inasmuch as young children are rarely attacked; while it is most prevalent among adults, and liability to it diminishes with advancing years.

Typhoid fever presents analogous conditions. The Eberth bacillus enters through the mouth and is lodged and developed in Peyer's glands. The chief differences are that the Eberth bacillus is not, like the diplococcus, capable of producing other diseases, and that the life period of the former is three to four weeks, while that of the latter is five to ten days. The analogy certainly holds with regard to the influence of depreciated constitution and age as etiological factors.

Analogy in Symptoms.—In pneumonia we have an increased leucocytosis, pyrexia, and more or less overwhelming of the nervous system, which is reflected to the heart, lungs, and other organs. The dyspnea is, I believe, more the expression of a special toxemia than of the crippling of the lung, because it is not always in proportion to the extent of the lesion, and it disappears at the crisis, while the lung is still greatly obstructed by the exudates. In addition, we have cough, which of course is due to the disturbance of the lungs and bronchi.

We have practically the same manifestations in typhoid fever, differing only in regard to the habitat of the microörganism, diarrhea taking the place of cough. The fever runs a different course because of the difference in the life-period of the organisms involved in each disease.

The most striking and important similarity is that the chief point of attack, in both diseases, is upon the nervous system; the toxemia resulting from the life and death of the microörganisms spends its chief force upon the nerve centers. This explains the well-recognized clinical fact that the general symptoms are rarely a correct index to the local lesion. Dyspnea and fever, especially, may be extreme, and the case may terminate fatally, with slight involvement of the lung, just as we may observe the most serious general condition in typhoid, without evidences of local lesion.

Crisis in croupous pneumonia is signalized by complete cessation of all the general symptoms, because the life-period of the microörganisms is terminated. And yet the lung remains more or less solidified by exudates, as is evident from the physical signs continuing. So do the general symptoms of typhoid fever cease with the cessation of the life-period of the Eberth bacillus, although the intestinal lesions are still so far from being removed that great care needs to be exercised with regard to diet, rest, and other preventive measures.

The *prognosis* of croupous pneumonia and typhoid fever bears close resemblance in many respects. The effect of previous mode of life, habits, and environment, before and during the illness, upon the issue of the case, is very much alike in both diseases, as is the influence of childhood upon the prognosis.

Having as briefly as possible in the time at my disposal traced the close analogy in the etiology, symptoms, and prognosis of these diseases, I propose to deduce from this analogy the expediency of following in pneumonia, as nearly as the differences indicated above may admit, the line of management which has afforded the best results in typhoid. We have learned from sad experience that the chief indication in typhoid fever is to enhance the patient's resisting capacity to the lethal agencies evolved by the infection-process.

It is my aim to emphasize a similar cause of action in pneumonia. The management of the pneumonic patient, which I propose to present to your consideration, is the result of an evolution from the methods, which some of you, like myself, have been taught, and which, doubtless, some of you, as I, have practised for years.

A distinct mental picture of my first case of croupous pneumonia rises before me. The patient was a young soldier, a hardy mountaineer, in whom a large portion of the right lung was consolidated. The chief surgeon of the hospital directed, as was the custom in 1862, flax-seed poultices to the chest, and a mercurial purgative, to be followed by nitrous powders, a preparation which is happily unknown to our recently graduated colleagues, consisting of 8 grains of nitrate of potassium with ½ grain of calomel and ⅛ grain of tartarized antimony, these powders to be administered every three hours until the gums were touched; *i. e.*, until ptyalism ensued. Wet cups to the chest were added to emphasize the doctors' blows upon the enemy—inflammation of the lungs—with a view to deplete the latter. The inflammation was resolving beautifully when the left lung was attacked. The same treatment was resorted to, with the exception of a blister being substituted for the wet cupping as a concession to the evidently enfeebled condition of the patient. This lung also was beginning to resolve, but the vital powers had been so exhausted by the depleting measures, that the system was unable to furnish the necessary conditions for restoration. The result was that the disease was practically cured, but the patient died from sheer depletion, as evidenced by a necrotic gray deposit on the blistered surface.

This result of what was the classical treatment at that time (1862), made a deep impression on my youthful mind as a crucial test, and I say it with some satisfaction that no patient of mine has ever been salivated or cupped, and very few blistered since that time. I continued for a long time to commence the treatment with a mercurial purge, to give veratrum to reduce the pulse, to poultice the chest for comfort to the patient, and to give small doses of tartar emetic as an expectorant, and morphin to allay the cough. But the teachings of Hughes Bennet Austin Flint, and Horatio C. Wood, gradually weaned me from this mildly spoliative practice. Until a few years ago I felt as helpless in a case of pneumonia as I did at that time in typhoid fever. Recovery in both diseases seemed to be the result of conditions over which my control was feeble or lacking. The patient's constitution, the type of the disease, and his environment played the chief *rôle*. Treatment was symptomatic in both diseases—expectant it was termed—and not inaptly, for I always expected something to happen which I seemed powerless to prevent. When I learned the true principles and value of the Brand method in typhoid fever, a positive treatment was at my command by which, *if called early*, serious and fatal complications, against which I had formerly felt impotent, could be prevented. For the comfort and the sense of security derived from this method, since I mastered its technic, I shall ever be grateful to its author. And herein I was recently corroborated by Gilman Thompson, Delafield, Ball, and Northrup in the "Section of Practice."[1]

It has been my ardent desire to reach a similarly comforting attitude in pneumonia. Weary of the expectant plan, and observing its enormous fatality, especially in those depreciated by faulty modes of life and habits, I looked to hydrotherapy for succor. While I cannot say that the latter has been reached to an entirely satisfactory degree, observation and reflection have produced a method of management whose clinical value deserves to be tested further.

The prevailing type of the disease should be carefully considered. It has been demonstrated by careful observers that the vaunted success of certain methods of treatment may be attributed to a change of type in the disease and the previous conditions of the patient. Any new treatment should therefore be approached with caution and judgment.

Dr. Leaming, whom many of you remember as a practical, safe clinician, gives a graphic delineation of this idea in his little book published in 1884.

"When I began my professional career, I believed, as I had been taught, that active interference was necessary in every step of this disease, to prevent destructive inflammation. But I soon found, and by accident, that cases would get well without active treatment; that the expectant plan and wise management was the best; simple medication, with stimulants and supporting alimentation. The mortality was so small that it seemed unnecessary for an uncomplicated case to reach a fatal result. When the fatal form of pneumonia began to occur in New York, I, with other physicians, was surprised at the failure of the managing method. The failure of the latter rendered a resort to the heroic method a necessity."

The type of pneumonia in this city appears to have remained as grave as it was in the time of which Leaming wrote. We still see and hear of cases dying rapidly. As recent sad illustrations in our own ranks may be cited the deaths of the lamented Loomis and of the brilliant young clinician Roosevelt. *In hospital and private practice this disease is more fatal than any other acute disease of adults.* In the New York City Board of Health statistics it ranks next to phthisis in fatality. I apprehend that the chief reason of this great fatality may be sought for and found in the helplessness of physicians in the presence of this fearful disease.

It follows, therefore, that the first consideration in the management of these cases is a due regard for the prevailing type.

Complete rest of body and mind, and good nursing, are essentials in furthering recovery. This cannot be too earnestly urged upon the patient and his family. The ventilation of the sick-room, too, which is much opposed by the laity, should be anxiously watched by the medical attendant, who is too prone to yield to existing prejudices, and thus to become an unwilling accomplice in depriving the patient of this greatest pabulum in infectious diseases—fresh, pure air. The patient and family should be positively assured that there is no danger of taking cold if the body temperature is elevated to any considerable extent. In summer and winter the air of the sick-room should be constantly renewed, even at the cost of reducing its temperature in winter to an extent which may be uncomfortable to the nurses. During the late war, cases of pneumonia treated in tents in rigorous weather did far better than those treated in improvised hospital buildings.

---

[1] *Med. Record*, November 7, 1896.

The diet should be restricted to milk and farinaceous broths, administered with precision, while the patient is awake, every two hours, in quantities ranging from four to eight ounces. I do not share the horror of asthenia in this disease, which is only too prevalent, and leads to undue feeding. The disease is of short duration ; it not infrequently suddenly attacks well-nourished persons in the midst of comparative good health. It seems an unphysiological proceeding to stuff these patients with concentrated foods, in large quantities, which they cannot assimilate, and thus to impose an additional tax upon the system. Stimulants, also, are rarely so necessary to the same extent as formerly, since the course of management here outlined was adopted. In alcoholic subjects whose consumption of liquor has been a daily habit and requirement, ½ to 2 ounces of good whisky every two or three hours may be useful, especially while resolution is going on, but not as a spur to a failing heart, as is commonly the practice. I am not quite sure on this point, hence still feel myself under the dominion of this idea. It would seem that inasmuch as a large part of alcohol is eliminated through the lungs, the latter are needlessly overburdened while they are straining to the utmost their functionary capacity. I should like to hear the experience of the fellows of the Academy upon this point.

Of medicinal agents I use but very few. Besides an opening dose of 10 to 20 grains of calomel, strychnin, and an occasional dose of morphin for pain, are the only medicines I have found of any real value. When the first sound of the heart becomes muffled or feeble, hypodermics of strychnin, $\frac{1}{30}$ to $\frac{1}{10}$ gr., every three or four hours, offer a valuable aid to tide the patient over a trying period. Given even to the production of trismus, if necessary, it is far superior to digitalis or brandy. I do not fear an occasional dose of phenacetin when the patient is restless, with high temperature, but it should not become a routine practice for temperature reduction. It is rarely required. Quinin, aconite, veratrum, digitalis, and other drugs, I have discarded after a prolonged trial.

The administration of calomel requires some detail. It should be placed, as Leaming and Cammann direct, dry upon the tongue and allowed to gradually disappear, being swallowed with the saliva, or, if necessary, washed down with a small quantity of water. These experienced practitioners tell us that "the inefficiency of the expectant method rendered a resort to the heroic a necessity, and with very encouraging results. Cases, such as had proved fatal by the mild treatment, were saved by the prompt exhibition of sedative doses of calomel, which are less depressing to the system than smaller doses." Today we are able to give a more rational explanation of the action of calomel in pneumonia than that of a "sedative." Its effect is twofold. First, it is a fact clearly established by Sternberg and others, that the diplococcus of Fraenkel, found most abundantly in the saliva, is destroyed by very feeble mercurial solutions. This may explain why the effect of calomel is so much more striking when allowed to slowly mingle with the saliva. Thus, the supply of microörganisms is at once cut off, together with toxins which would continue to be evolved from these, so long as they are living. This is not an unreasonable explanation of the remarkably rapid change in the symptoms of even desperate cases which are reported by Leaming, and which I have observed.

Secondly, a large dose of calomel removes ptomains that may have lodged in the gastrointestinal canal. Calomel is the only agent to which investigations (made before guaiacol was discovered) have conceded internal antiseptic properties. Moreover, it clears the *primæ viæ*, as we older practitioners were taught to do; it clears the ship for action, as it were. It also disgorges the portal circulation, and probably thus relieves the stasis existing in the pulmonary circulation indirectly. Be the explanation what it may, clinical observation in typhoid fever, pneumonia, tonsillitis, diphtheria, and other infectious diseases has convinced me of its value when given in one large dose in the beginning of the case. It very rarely produces serious purgation. Even when diarrhea exists, it does not salivate as readily as smaller doses, and it certainly requires no repetition. It is more easily retained by an irritable stomach than other medicines. It is my custom to direct the patient to rinse the mouth frequently with a saturated solution of potassium chlorate to insure against ptyalism, and to keep the mouth in a clean condition. Juergensen recommends weak mercurial solutions as a mouth-wash for the purpose of destroying the diplococci, whose favorite habitat is in the mouth.

Hydrotherapy, judiciously adapted to the indications of the case, has proven a valuable auxiliary in the management of these patients. In the croupous pneumonia of children, who are more easily handled, without great disturbance, the tub-bath is very useful when administered alongside of the bed, as in typhoid fever. The temperature should, however, rarely be below 85° F. Beginning with 95°, each bath may be reduced a few degrees, until the patient becomes accustomed to it, repeating every four hours until the temperature remains below 102.5°. Friction is a *sine qua non*, because chilling is more apt to occur in these patients than in typhoid fever, and for this reason the duration of the bath should be short—eight to ten minutes. The toxic agents which are operative in pneumonia appear to affect the heat-center quite differently from those evolved in typhoid fever. A bath of 80° F. often reduces the temperature in the former disease two to four degrees, while in the latter one degree would be a large reduction. Upon this clinical fact I have based a diagnostic bath which materially aids in the differentiation of typhoid fever from other diseases which so strongly resemble it during the first week. The value of the full bath in the pneumonia of children has been confirmed by the highest authorities, such as Penzoldt and Baginsky in Germany, Hutinel of Paris, our own Jacobi, and others.

In adults, however, I have given up tub-baths, although very cold baths (50°–60°F.) have been lauded by Juergensen and commended (65° F.) by chief-surgeon Vogl of Munich in a letter to myself. While they proved useful in many cases, I am convinced that the disturbance and agitation incident to a cold tub-bath increase the lung disturbance. If the patient is very dull, cyanotic, and presents great nerve prostration, resembling the typhoid state, I do not hesitate to choose between the two evils, an increase of the local disturbance and a decrease of nerve prostration, by plunging the patient into a bath of 80° F., or less, or seating him in water at 100° and and pouring several basins of water at 65° to 75° F. over his head and shoulders. This is a valuable heart tonic. It serves, by deepening the inspirations, to dislodge accumulations in the bronchi, which have crippled the healthy as well as the affected lung.

The most useful hydriatric procedure in pneumonia is the *wet compress*. This consists of three folds of thin old linen stitched together at the edges, which has slits corresponding to the axillæ, so that it may be wrapped around the patient's chest snugly. The slits are made sufficiently deep to allow the upper edge of the compress to reach above the clavicles, and admit of the junction of the flaps thus formed on each side to cover the shoulders. Two such jackets, and two pieces of closely woven thin flannel of the same shape, but an inch wider and longer, should be provided and fitted to the patient. One of the former is rolled up and soaked in a basin of water at 60° F., and wrung out so that it remains quite damp without dripping. The flannel is now spread out upon an even surface and the wet compress put upon it, so that there remains an edge of flannel about an inch wide all around. Both are rolled together half-way. While the patient is gently turned upon his left side, with the precaution of not allowing any exertion on his part, the compress is so placed upon the bed that the rolled part lies in close proximity to the left side of the patient, and the lower edge of the left slit is under the left axilla. Now the patient is quietly turned upon his back, so as to release the rolled-up portion. The latter is now unrolled, and both edges of the compress are brought forward upon the front of the chest and are thus made to envelop the latter snugly. The flannel cover, which has been allowed to lie upon the bed during the application of the wet compress, is now brought forward so as to quite cover the latter. It is secured by two safety-pins in front, and one upon each shoulder.

The well-known oiled silk jacket may serve as a model for the shape and manner of applying this wet compress. The latter should be changed every half-hour, unless the patient's temperature is below 102.5° F.; every hour unless it be 99.5° F., when it is discontinued. The removal is accomplished by preparing the second compress just like the first, paying attention to the water temperature being 60° F. When it and the flannel covering are rolled up in readiness, the first compress is removed and the second is applied. Thus a rotation is kept up every half-hour or hour as the case may require, night and day, unless the patient be asleep. The water in the basin should be renewed each time, and the compress rinsed off in another basin before it is rolled up for soaking, in order to insure thorough cleanliness and prevent furnuncles by furthering asepsis.

The technic of the procedure has been entered into with a detail that may seem needless. As will be shown later, these details insure precision, and upon their exact execution may depend success or failure. The physician should himself supervise the first application, just as he should supervise the first Brand bath in typhoid fever. A skilled nurse can apply these compresses with a minimum of disturbance.

There is need, too, of individualization. In the average case a temperature of 60° F. will be appropriate. Should the patient evince stupor or muttering delirium, a lower temperature should be adopted, and the chest should receive one or more dashes of colder water, before renewal of each compress. The same procedure is useful in bronchopneumonia, when the bronchi are blocked by secretions, or cyanosis exists. In a case which I had the privilege of seeing with Dr. E. J. Ware, this application proved its worth. The patient had passed through an attack of typhoid fever lasting some ten weeks; her condition was so precarious that when I entered an adjoining room she was bidding her relatives adieu. By skilful management she had been sustained up to this time. The right lung in its entire posterior aspect was solidified. The temperature was usually below 102° F., and the pulse exceedingly rapid. There was no dyspnea.

In this case the modified procedure referred to was extremely valuable. Inspiration soon deepened, the heart slowed, and in a few days the patient rallied from a most desperate condition.

A higher temperature than 60° F. may be used if there be much jactitation, insomnia, or excitability. In the latter event great benefit will accrue from allowing the compress to remain two hours and moistening it more thoroughly, which converts the compress into a soothing fomentation that is not relaxing like a poultice.

In a colleague, whom I had the privilege of seeing with Dr. Palmer Cole, there was complete involvement of the entire right lung, with temperature ranging from 103° to 105° F., the heart action being fair. The patient being a morphin *habitué*, there was a decided neurotic element in the case, involving insomnia and great jactitation. The compresses were only applied hourly, despite the high temperature, but they were allowed to be quite moist, in order to obtain a calming effect. Although the left lung became involved later, Dr. Cole informed me that the patient recovered from his desperate condition, and that, in his opinion, his life was saved by the management here outlined. No remedial measure deserves adoption by the profession unless the *rationale* can be satisfactorily explained.

According to my view of pneumonia crouposa, the therapeutic indications are (1) to stimulate and invigorate the nerve centers with a view to enhancing the patient's vital powers, (2) to prevent and control heart failure, (3) to reduce temperature, (4) to eliminate toxins.

The nerve centers are well stimulated and rehabilitated by the repeated gentle shocks and subsequent reactive stimulation of the sensory fibers in the skin, both of which are conveyed to the central nervous system and thence reflected to the organs, upon whose functionating capacity depends the patient's ability to resist the toxic agencies circulating in the blood. We aim here to accomplish precisely the same object as with the Brand bath in typhoid fever. The milder form of shock is better adapted to pneumonia, because it is less disturbing, and because the toxemia, induced by the diplococcus, is less intense in the average case, and certainly has only one-third of the life period of the Eberth bacillus.

After a few compresses the patient grows more calm, the inspirations, which are deepened by each application, continue deeper, dyspnea is markedly relieved, sleep ensues, appetite improves, and the skin and kidneys begin to act more freely. These clinical evidences demonstrate the correctness of the *rationale* enunciated above.

The maintenance of the heart action is accomplished by the wet compresses in the following manner: When the cold compress is applied, there is a rapid contraction of the cutaneous vessels, which raises the tension at once, but gives way to a tonic dilatation of these vessels, which is evidenced by a ruddy hue of the skin. This dilatation differs very decidedly from that relaxed condition of the cutaneous vessels produced by warm poultices. The latter relax the vaso-constrictors, producing a paretic condition of the vessels, or a stasis, while cold applications stimulate the vaso-dilators, giving rise to an active dilatation, with maintenance of the tone of the vessels, an active hyperemia, by reason of which the blood is propelled more vigorously through them. The heart is thus relieved; not by a *vis-a-tergo*, as is the case after digitalis, but by a *vis-a-fronte*, formed by broadening of the blood-stream in the cutaneous capillaries, whose enhanced tonicity aid at the same time in propelling the blood onward. Arterial tension is increased, as is evidenced by the better filling of the radial arteries. The right heart is indirectly aided by this enhancement of the general tone in the vascular apparatus, and may thus expend more force upon the pulmonary circulation, whose vessels contract more firmly by reason of the dilatation of the superficial vessels.

Romberg[1] has recently confirmed what I have, several years ago, and repeatedly since that time, insisted upon, that in acute infectious diseases we encounter disturbances of the circulation which manifest themselves clinically as reduced tension and diminished filling of the arteries, and which are commonly described as heart failure. Undoubtedly the condition of the peripheral vessels bears a very large share in the production of cardiac atony, as I have sought to impress when explaining the *rationale* of cold applications in typhoid fever and pneumonia.[2] Romberg has shown by experiments with injections into rabbits of Fraenkel's diplococci that the circulation is damaged by a paralysis of the vasomotors, while the heart itself remains unaffected. It is true that the right ventricle is overloaded because of lung infiltration, but that this does not so seriously cripple the heart as is generally supposed is proved by the fact, referred to above, that when crisis ensues, the compression due to the exudates is not removed at once, and yet the respiration and circulation are relieved as if by magic. This can only be accounted for, if I may be allowed to reiterate so important a statement, by the nervous system being suddenly relieved of the toxic elements generated by the diplococcus, whose activity ceases at once when it has reached the end of its natural life-period. It is probable that crisis ensues when the antitoxins evolved in the natural course of the disease have attained an overbalance of power. The battle between the diplococcus, with its allies, and the patient's vital powers, is at an end. The most important effect of cold applications in pneumonia is, therefore, the aid and sustenance they furnish to the nervous system, which bears the brunt of the fight. The improvement of cardiac action is one of the results of this effect.

[2] "Uses of Water," vol. ii, p. 166.

Reduction of temperature is an important therapeutic element in these cases. Persistent high temperature may enfeeble the heart, and certainly depreciates the nerve centers. Some good clinicians, like Juergensen, claim that high temperature is the chief danger to patients suffering from pneumonia, and he advises in his latest work[1] that very cold baths, some below 60° F., are demanded to meet this "great danger." I shall not discuss this doctrine fully to-night. Since my argument against it before the New York State Medical Society in 1889, I have repeatedly expressed adverse views in this and other societies to this unfortunately too firmly established error, an error which has given unhappy prominence to the coal-tar antipyretics in the therapy of fevers. If any further testimony is needed to lay this ghost, which has so long affrighted timid practitioners, to rest, the discussion on fever in the Fourteenth Congress of Internal Medicine in April, 1896, demonstrates that we should cease to regard elevation of temperature as the cardinal symptom for therapeutic attack. While, however, these conclusions fully corroborate my own views expressed eight years ago, I may say that high temperature, though not actually and directly a lethal factor by inducing fatty degeneration of the cardiac muscular fiber, as claimed by Ziegler and others, does seriously cripple the work of the heart by imposing upon it more rapid action, and it does seriously interfere with the patient's comfort. High temperature, therefore, demands careful attention by measures that are not harmful like the routine use of coal-tar antipyretics. As I said elsewhere, I do not hesitate to use the latter occasionally when high temperature is associated with sleeplessness or great jactitation. They give great comfort to the patient, and are less annoying and disturbing than the wet compresses. But the latter are not used by me for their antithermic effect, which is only incidental.

The susceptibility of pneumonia patients to cold baths, and the great facility with which their temperature may be reduced, renders great care in the application of these measures imperative. For this reason I have abandoned cold baths, and have dwelt so minutely upon the method of application. That so mild a procedure as the wet compresses should be capable of reducing high temperatures in pneumonia, I have numerous charts to demonstrate. The decline is not as rapid as after cold baths, but it is pronounced and steady. It does not ensue after one or more compresses, nor does it follow the course of temperature reduction observed after cold baths in typhoid fever.

It decreases day by day one or more degrees. It is not the result of direct refrigeration; such an effect is neither aimed at nor obtainable. When a compress at 60° F. covered with flannel is applied around the chest of a pneumonia patient who presents a temperature of 102° to 106° F., there is an immediate cooling of the surface covered by it, which is followed by a gradual reaction with a more or less rapid rise of the surface temperature, until the latter is nearly the same as it was previous to the application. The surface is now bathed in a vapor produced by the heating of the compress. If the latter be allowed to remain sufficiently long, the flannel covering receives the vaporized water, and passes it outward until the compress becomes dry. But if the compress is changed as indicated above, the vapor is more slowly removed, and the skin and compress are found to be cooler than the flannel covering. Thus the gradual cooling process is continued until a fresh, cold compress is applied, when the skin, more sensitive by reason of having been bathed in this warm vapor, feels the shock more distinctly and reacts more fully. The error is not infrequently committed of covering a wet compress with oiled silk. While this would protect the bed and clothing of the patient, it would defeat the object of the compress by converting it into a poultice. If the body temperature is 103° F. or over, the compress applied as above becomes warm in half an hour, although evaporation of the moisture through the flannel renders the skin under it cooler than other parts of the body. When it is renewed, the repetition of the gentle shock and tonic dilatation occurs. Thus a slow cooling process, not relaxing or in any way depreciating, is maintained, which gradually lowers the general temperature, calms the patient, and contributes much to his recovery.

---

[1] Penzoldt and Stinzing, "Allgemeine Therapie," 1896.

How far this cutaneous hyperemia acts as a revulsive, it is impossible to ascertain, but it is a well-known fact that such hyperemia is always accompanied by contraction of the blood-vessels in the parts underlying. Thus may a favorable effect be produced also upon the inflamed lung tissue, and its circulation be improved.

The elimination of toxins is promoted by the wet compress, as by all cold hydriatric procedures. It has been proved by Roque and Weil that the urotoxic coefficient of the urine is trebled after cold baths in typhoid fever. All the secretions of the body are increased by cold applications. The alkalinity of the blood is also enhanced by the latter, as demonstrated by Alois Strasser. Tassinari (quoted by Winternitz) says that after septic infection of rabbits, the alkalinity of the blood is reduced about one-half. And it has been shown by others that in all infectious diseases the blood is less alkaline. Since alkalinity of the blood is a prerequisite for the existence and activity of phagocytes, it is not unreasonable to assume that cold applications further the phagocytosis, and elimination of toxic products, by rendering the blood more alkaline. Hence Buchner is correct (as Winternitz claims) in asserting that by cold-water treatment the powers of resistance to infectious agencies are enhanced.

This antitoxic-eliminating effect is increased by copious libations of water. It is my custom to administer in pneumonia, as in typhoid fever, 6 ounces of water every two hours, alternating with the same quantity of milk, night and day, when the patient is awake. The enormous increase of urine is scarcely credible. I have charts showing from 60 to 122 ounces in twenty-four hours. Some of the well-trained nurses, who have seen much hospital service, have volunteered an assurance of the correctness of their reports, under the impression that I would discredit such large quantities.

There is a striking peculiarity impressed upon the regular course of croupous pneumonia by the method here outlined to which I desire to call attention. Although the fever, dyspnea, and other distressing manifestations yield, to a remarkable extent, in a large proportion of cases, in one or two days, the physical signs do not change in a proportionate degree. Indeed, I have observed a distinct crisis in only about forty per cent. of the cases so treated; in the remainder, the disease ended by lysis of a very slow type. Improvement of the general symptoms goes on, the patient seems well, and is anxious to rise, but a dull percussion-note, muffled breath-sounds, and bronchial whisper bear testimony to lingering exudates for many days.

As an example, I may cite the case of H. E., who sickened on December 8, 1895. His temperature ranged from 102° to 104° F. for four days, without any pronounced physical signs in the lungs, which were examined every day. On December 12th, consolidation of the entire posterior lower half of the right lung was made out. The mouth temperature was 104° F. at three P.M.; cough had been distressing several days; there were now rusty sputum and increased dyspnea. The family being greatly alarmed, Dr. A. A. Smith was called in consultation, but did not see the patient until the next morning. Calomel having been administered, the wet compresses were now applied, with the effect of bringing the temperature down two degrees in five hours. During the night, the compresses were, by a misunderstanding of the nurse, renewed every hour. The patient sleeping soundly for the first time since his illness, complained to me of the frequent disturbance. After twelve compresses, the temperature was 101° F. at eight A.M. When Dr. Smith saw him, at ten o'clock, he found him so comfortable that he expressed surprise at being called, and concurred in the treatment. Physical signs of consolidation were distinct. There had been no other treatment except 5 drops of dilute hydrochloric acid every two hours, as a placebo, followed by 6 ounces of water. Temperature reached normal point once every day for two days, and remained normal for ten days, when the patient was dismissed. Physical signs continued during Dr. Smith's attendance of five days, and dulness of the percussion-note had not entirely cleared up when I last saw him.

Clinical results confirm the *rationale* of this treatment, and attest its value. A quarter of a century ago the greatest living German clinician, Professor Niemeyer said:[1] "I have made extensive employment of cold in the treatment of pneumonia, and, relying upon a large number of very favorable results, can recommend the procedure. In all cases, I cover the chest of the patient, and the affected side in particular, with cloths, which have been dipped in cold water, and well wrung out. . . . In the hospital at Prague, every pneumonia is treated with cold compresses and, according to the statement of Smoler, it is exceptional for a patient not to feel material relief from the treatment."

Why has a treatment which has received high commendation by so eminent a teacher not become an established practice in a disease which so often baffles the physician under other management?

To the student of the history of hydrotherapy this question is not difficult. Although water is an orthodox remedy, to which Hippocrates devoted almost an entire book, and although it has been highly commended by eminent physicians at various times, it has not become the common property of the profession, because most of those who taught its use and value most earnestly failed to give definite directions for its application. Niemeyer illustrates this point. He simply advises "cloths wrung out of cold water to be applied to the chest" of the pneumonic patient. The temperature of the water, the duration, technic, frequency of repetition are left to the discretion and good or bad judgment of his hearers and readers, and yet these are far more important in hydrotherapy than are the dose, time of administration, frequency, etc., in prescribing medicinal agents.

---

[1] "Text-book of Practical Medicine," vol. i, p. 185, translated by Humphreys and Hackley.

In a paper on pneumonia, published several years ago by an eminent American teacher, the following sentence occurs: "If the temperature in pneumonia "rises to 104°, 105°, or 106° F., I use cold baths or "cold packs." Such indefiniteness is to be greatly deprecated when coming from one who is highly regarded as a teacher and guide. A cold bath, without stated temperature, is generally understood to be a bath to which neither hot water nor ice has been added. Such a bath would have a temperature of 75° F. in August, and 45° F. in December, in this city. Thirty degrees in the temperature of a bath are capable of producing an immense difference for good or evil; in pneumonia it would react very unfavorably, according to my personal observation. Just as Niemeyer failed to create a permanent following for the practice which he so highly lauded, so has the justly famous teacher referred to failed to impress upon the profession a practice which he had taught in 1870, as follows: "If there be anything I should rely on in "pneumonia, if the temperature is very high, it is "cold-water treatment." If this excellent teacher had been as explicit in giving temperature, duration, etc., of the "cold-water treatment," as he was in giving the doses of digitalis, nitroglycerin, and camphor, the valuable lessons he endeavored to inculcate would not now (twenty-five years later) require to be taught anew; they would have served as a beacon-light to the vain searcher after reliable therapeutic methods in this fatal disease. Let me emphasize, therefore, that while I may have offered nothing novel or striking in this essay, its chief aim is to impress upon you the great import of giving definite prescriptions for all hydriatric measures in this as in other diseases, be they acute or chronic, for only by such precision may we obtain definite results.

Statistical evidence to prove the value of the measures here advocated, or of any other method of management, is indeed very difficult to produce. The type of the disease differs very much; in private practice the number of cases is too meager, and observations are too inaccurate and unreliable. I may say, however, that I have not lost a case of uncomplicated croupous pneumonia in private practice since the adoption of the management of patients suffering from it, here outlined. In hospital work the chief element of success with this method, *viz.*, its application in the early stages of pneumonia, is unfortunately absent. Its favorable influence upon the progress of the disease is attested, however, by the statistics of 156 cases in the J. Hood Wright Memorial (formerly Manhattan General) Hospital, in which the total mortality from pneumonia has been reduced one-half, since the method here advocated has been adopted by the entire staff; while in the cases admitted before the fifth day the mortality has been twelve per cent. against thirty-seven per cent. under the formerly prevailing expectant plan. These cases were under the observation and treatment of my colleagues, Drs. Daniels and Knickerbocker, and myself. The method described above is, with slight modifications, equally favorable in catarrhal pneumonia.

The ice-pack method recently advocated by Dr. Mays of Philadelphia, which claims a mortality of 3.58 per cent. in private practice, is worthy of mention in this connection, because its success is applicaable upon the theory that it fulfils all the therapeutic indications almost as well as the cold wet compresses. Ice is applied in bags which are wrapped in towels and placed over the affected area, with a view to reduce the inflammatory process in the lung by direct cold. That the latter is an erroneous idea has been proven by the experiments of Silex,[1] who has shown by experiments on animals, that "ice applications increase the "temperature of the organs over which they were "placed and which were to be cooled." This effect of local cold has long been recognized by hydrotherapists, who know that intense cold applied externally produces a compensatory hyperemia in the parts beneath, thus protecting the latter against destruction if carried too far. The *rationale* of the favorable influence of the ice-compress treatment, however, is not difficult to explain upon recognized principles of hydrotherapy.

The towels which envelop the bags of ice soon become thoroughly wet by condensation, and thus the application is practically a continuous wet compress. This together with its unevenness prevents the complete reaction which is so useful in arousing the nerve centers, but its being applied upon parts of the chest only prevents serious results from this source. The objection to ice compresses would seem to be their uneven surfaces, which renders them uncomfortable when applied to the posterior portions of the lungs, the patient lying on the back; and also that their weight when applied anteriorly must render them inconvenient. In consideration of these facts I have not felt justified in applying this method of ice packs so long as good results were obtained from the wet compresses.

---

[1] *Münchener mediz. Wochenschrift*, 1893.

In conclusion I hope to have shown that

1. Pneumonia is, like typhoid fever, an infectious disease whose chief attack is upon the nervous system, as manifested by heart failure, and other signs.

2. The treatment should be applied, not to the disease, but to the patient, whose resisting capacity should be enhanced by all useful remedial agencies.

3. Calomel in a large dose, followed by wet compresses, adapted in duration and temperature to each case, with fluid diet, and an abundance of water internally, aided, if need be, by mild alcoholic stimulation and hypodermics of strychnin, offer at the present time the most favorable, yet not perfect, results in the management of patients suffering from pneumonia.

SOME DIAGNOSTIC CONSIDERATIONS OF HEMATOLOGY.[1]

By ARTHUR J. PATEK, M.D.,
OF MILWAUKEE.

It is my intention to touch lightly on hematologic conditions that have been pretty thoroughly studied and present well-known clinical pictures, such as simple and pernicious anemia, chlorosis, and leukemia, and to leave unmentioned those branches of this science that have to deal with the methods of preparing and staining blood-preparations for investigation. I wish only to call attention to some of the diagnostic considerations of hematology with reference more especially to their application in diseases that are not purely affections of the hematopoietic system.

The blood, in addition to being the bearer of products to tissues for elaboration, and of elaborated products from tissues, is the carrier of many infectious germs, as the streptococcus and staphylococcus in septic conditions, the bacillus of relapsing fever, the typhoid bacillus, the gonococcus, and also of the ptomains elaborated by these and other bacteria. It harbors animal parasites, as the plasmodium malariæ and *filaria sanguinis hominis;* its own elements may demonstrate disease, as in the essential blood-affections—chlorosis, progressive pernicious anemia, and leukemia, in which these diseases are made manifest by abnormalities of the hemal constituents.

That the claim that hematology should be added to the symptomatology of all diseases not distinctly of a local character is not overzealous enthusiasm, is shown by the efforts that are being made to place it on a more sound footing and to enlist its services in the general study of disease. This labor has not been entirely fruitless, for though the list of diseases of which we have a definite hematologic knowledge is a small one, and our knowledge of the blood-elements is still very limited, yet careful observations and experiments by tireless workers have enabled them to formulate generalizations as to the symptomatology of the blood, which may act as valuable aids in diagnosis in certain obscure cases.

Without going into etiologic details, I wish to call your attention to a new granulation-cell discovered by Professor Neusser of Vienna, and demonstrated by him at the Medical Congress at Vienna in September, 1894. These granules are characterized as "perinuclear basophils," because they are basic as to their staining affinities, and perinuclear as to their grouping in the cell. You will find an exquisite specimen under the microscope. This preparation I have made from the blood of a lady who has been gouty for over thirty years. Neusser considers this cell diagnostic of uric-acid diathesis in its various pronounced and masked forms, having found it present in a large number of such cases, and achieved some success in directing his therapeusis accordingly. The granules he considers derivatives of the cell-nucleus, hence nuclein-products—advance-stages in uric-acid formation, the accumulation of which in the system gives rise to the various symptoms found in this diathesis.[1] Further investigations, however, are called for, and at the recent meeting of the American Medical Association in Atlanta, Osler announced that a report on this subject was in course of preparation.

In a general way, the affections in which the constitution of the blood may prove an objective symptom, having distinct bearing upon the diagnosis, may be classified as: (1) Acute febrile affections and suppurative processes; (2) malignant processes.

It is far from possible to claim that hematologic distinctions exist between these affections and their subdivisions, but the value of the science lies in the generalizations of which it admits, and its application as a measure of differential diagnosis.

We may lay down the general rule that in the acute febrile affections (including under this head the various infectious diseases and acute suppurating processes) there exists a leucocytosis. It is the exceptions to this that assist us in a differential diagnosis. We may lay down a second broad rule governing the infectious fevers, *viz.*, that in addition to a leucocytosis there is to be noticed either no increase, a diminution, or an absence of eosinophil cells at the height of the fever, the exceptions to this rule being scarlet fever, malaria, and tetanus. Acute suppurative processes, wherever they may exist, adhere quite closely to the rule of existing leucocytosis, and we may often find it of service to know that we are dealing with a pleurisy or meningitis of purulent type, or an abscess of the liver. The infectious fevers display greater deviations, and we shall take up the important ones individually.

---

[1] Read by invitation before the Milwaukee Medical Society, June 23, 1896.

Croupous Pneumonia.—Leucocytosis is very marked and confined largely to the polynuclear elements. The greater the leucocytosis, the better the prognosis, and, *vice versa*, the fewer the leucocytes, the worse the prognosis. A long-continued, high degree of leucocytosis is, however, unfavorable, being suggestive of a complication, such as general sepsis. Ewing[2] says that, out of 101 cases, "not one case recovered in which the disease was of even moderate severity when the number of leucocytes fell below 14,000," and A. H. Smith of New York corroborated this observation in an address on "Prognosis in Pneumonia," delivered at the recent meeting of the Association of American Physicians, in Washington. Cases of excessive leucocytosis gave an unfavorable prognosis, being due to septic conditions, in one case to an empyema. This leucocytosis is confined to the neutrophil cells, for the eosinophil cells are diminished or absent, reappearing immediately before, during, or after the crisis. They may, therefore, if appearing before the crisis, be a means of predicting this event; after the crisis, the number of the leucocytes becomes normal—often critically with the fever. A pseudo-crisis is not attended by a diminution of leucocytes or a reappearance of eosinophils.

Typhoid Fever.—Opposed to the positive blood-picture of pneumonia, typhoid interests us because of its negative sides. Here we find a uniform diminution of the white corpuscular elements, a leucopenia (dearth of white corpuscles) affecting principally the polynuclear elements. Their number may be as low as 1500 or 1700, in place of the normal 7000 or 9000, their reappearance following the return of the normal temperature. We are frequently confronted with the perplexing question: Are we dealing with a central pneumonia or a typhoid fever? Let these points, then, come to our assistance: Examination of the blood for its leucocytes (including eosinophils) and its fibrin (increased in pneumonia), the sputum for its eosinophils (absent in pneumonia), the urine for its chlorids (diminished in pneumonia), and for the diazo-reaction (very often present in typhoid). A combination of the affections—typhoid and pneumonia—will, of course, give us a mixed, hence, atypical picture. So uniformly is leucopenia present in typhoid fever that a leucocytosis in the course of the disease should always be regarded with great suspicion. Widal's method, based on the looping of bacilli observable in the blood of a typhoid patient, gives promise of an absolute diagnosis of typhoid.

Acute miliary Tuberculosis.—There is no characteristic blood-picture here that gives us any assistance, and alas! we are not brought nearer a solution of the difficult problem of the differential diagnosis between miliary tuberculosis and typhoid fever. It has been thought that the diminution of leucocytes in typhoid and the absence of this in miliary tuberculosis would be of assistance. In some cases this has been found serviceable, and more recent reports show that there is no constancy in the hematology of miliary tuberculosis. Two carefully observed cases[3] reported by Warthin of Ann Arbor showed a constant diminution of leucocytes, and thus we find ourselves as much at sea as before, and more likely to be misled than aided if arguing from the constancy of the hemal condition in typhoid.

Pulmonary Tuberculosis shows a leucocytosis only in the ulcerative form, and we are, by reason of this, justified in diagnosticating a cavity-formation, even though the physical signs be absent, providing there be no other chronic suppurative or exudative process.

Meningitis, tubercular and purulent.—Purulent meningitis usually has an evident cause—trauma, aural or nasal disease, etc. When we consider the number of cases of chronic otitis media that actually exist, we must say that meningitis from this source is comparatively infrequent; and yet, tubercular meningitis may attack an individual suffering from chronic otitis media, and thus obscure the diagnosis. I have seen two such cases in which eminent clinicians were baffled. Unfortunately, the blood is not of so great an assistance here, for there is no constancy in the leucocytosis. But in purulent meningitis it is of the utmost importance. An interesting case, occurring in Vienna, has been reported by Singer.[4] A patient with otorrhea of many years' standing was suddenly seized with fever and symptoms strongly suggestive of meningitis. The existence of a leucopenia cast suspicion upon the case, and later the discovery of the typhoid bacillus in the urine cleared the diagnosis and prevented operative intervention, to which the patient would have been submitted if the diagnosis of meningitis had been made.

The constancy of the leucopenia in typhoid and non-existence in tubercular meningitis may frequently be of material assistance in diagnosis.

Scarlet Fever.—Of the exanthematous fevers, this shows the most marked blood-changes, a pronounced leucocytosis being found several days before the appearance of the eruption. The polynuclear cells predominate (constituting nearly ninety per cent. of all, and eosinophils are also in large excess, both relatively and absolutely, their excess being looked upon as prognostically good. During the predominance of the catarrhal symptoms in the preëruptive stage, when an absolute diagnosis from measles is impossible, or at best very doubtful, this hematological condition may serve to discriminate between the two diseases. In measles, there is no appreciable leucocytotic alteration of the blood. The same may be said of malaria (in its acute form), typhus, influenza, and, as has already been mentioned, tubercular meningitis.

Malaria and Sepsis.—Absence of a leucocytosis and of eosinophil cells in malaria may, when there are no typical chills, be of service in differentiation from sepsis.

Diphtheria shows quite a marked increase of leucocytes, and erysipelas resembles pneumonia in a critical decline of its leucocytes. Osteomyelitis is also characterized by a marked leucocytosis.

It will be noticed that the distinctly pathologic hemal conditions are largely limited to those infectious processes that are characterized in part by inflammatory exudations.[5]

Bremer[6] of St. Louis claims to have found with the use of a specially prepared eosin-methylblue stain a characteristic pigmentation of the red corpuscle in fifty cases of diabetes. This awaits corroboration.

Secondary Anemia offers nothing characteristic, and is found associated with a large number of chronic affections, such as lues, nephritis, rachitis, malignant tumors, bone-affections, uratic diathesis, etc.

Malignant new Growths.—We may make the general statement that, in addition to the secondary anemia, these conditions incline to a leucocytosis. A very malignant sarcoma may develop an enormous degree of leucocytosis. An ulcerating tumor is especially prone to give rise to a leucocytosis, and this rule is of much practical importance, serving as an excellent guide to the operability of a concealed tumor, such as a carcinoma of the stomach, but a marked leucocytosis is a contraindication to operation. A mild degree of leucocytosis is usually present in any case, and is thus, if in combination with other dubious symptoms, of early diagnostic value. When there is associated with gastric cancer an atrophy of the gastric glandular apparatus, the secondary anemia may be so great as to constitute a pernicious anemia. The experimental fact recently corroborated by Paul Meyer[7] that the ingestion of nuclein normally causes a leucocytosis has also been made use of in the diagnosis of carcinoma ventriculi, for, owing to deficient absorptive powers, a leucocytosis does not here follow the ingestion of nuclein. We may also cite the fact that the digestive leucocytosis, which, in normal individuals, may be estimated as high as 20,000 white corpuscles, is also frequently absent in gastric carcinoma, though, as very recently pointed out by Hassman of Vienna,[8] digestion leucocytosis as a diagnostic symptom in carcinoma ventriculi, is of value only if it is coexistent with an absence of peptonizing power, *i. e.*, the difference between the digestion-leucocytosis in ulcus and carcinoma is to be sought in the concomitant anatomical changes of the gastric mucous membrane, these usually being severe in carcinoma and mild in ulcus.

Parasitization with *Bothriocephalus latus*, severe lues, exhaustive hematemesis, and carcinoma cachexia may present the picture of a pernicious anemia.

To sum up, then, let us make the following generalization: With the exceptions as noted, and with definite limitations, an examination of the blood may assist in the differential diagnosis of:

Typhoid fever and pneumonia; typhoid fever and tubercular meningitis; typhoid fever and typhus fever; tubercular and purulent meningitis; scarlet fever and measles; scarlet fever and diphtheria; malaria and sepsis; carcinoma, ulcerating and non-ulcerating; purulent and serous deposits.

These considerations are meant rather in the light of diagnostic possibilities based on our present limited knowledge of the subject, and I have therefore attempted to treat this subject conservatively. My sole desire has been to stimulate observation and investigation on the part of the individual, by presenting evidence to show that hematology embraces a broad field, not limited to rare blood-affections, nor restricted in practical application to the scientist and his laboratory, and that there are diseases daily passing under the eyes of practitioners in which an examination of the blood may prove a serviceable procedure, adding not only to the symptomatology of the disease, but aiding in the diagnosis.

New Jersey's Sanitary Commission. — An important meeting of this commission occurred at Lakewood recently at which many details relating to unsanitary conditions in the numerous factories of the State were discussed. An effort will be made this winter to pass such legislative measures as will in a large degree correct these defects.

HYSTERICAL FEVER.

BY W. GILMAN THOMPSON, M.D.,
OF NEW YORK.

IN the MEDICAL NEWS of December 19, 1896, page 700, is reported a case of "hysterical fever," in which the temperature (rectal) was 112° F. (44.4° C.). Dr. Alexander Smith, in exhibiting the patient during a clinical lecture, gives credence to the possibility of the existence of much higher temperatures, and refers to "a case reported by a gentleman of high authority, in which the temperature of a male patient rose to 122° F." (50° C.), and to another case reported at a meeting of the Association of American Physicians, in which the temperature was said to reach 148° F. [*sic*] (64.4° C.). Dr. Smith adds: "In each of these cases there was an hysterical element." I do not deny the existence of a possible temperature of 112° F. in anyone, but it is to be regretted that further publicity should be given to the report of the alleged phenomenon of much higher temperatures than this, which is as definitely controverted by the established facts of physiology as have been the assertions that air at 450° F. (232.22° C.) could be drawn into the depths of the lungs, or that inhalation of pure oxygen gas would cause convulsions by rapid oxidation of all the body tissues!

Many cases similar to the one reported by Dr. Smith have been recorded, and, as he says, the majority of them have been in hysterical subjects or, I may add, in malingerers. Recovery from a temperature of 112° F. is quite possible in insolation. I have seen three such cases. The forthcoming annual report of the Presbyterian Hospital, New York, will contain the records of several similar cases, and of one in which the temperature rose to 115° F. (46.11° C.), the patient recovering. During the unprecedented heat of last summer (1896), I am told that a patient suffering from sunstroke was received at the New York Hospital, who lived for three days after having had a body temperature of 117° F. (47.22° C.). All such cases are attended by phenomena too well known to necessitate detailed repetition here. Coma, convulsions, Cheyne-Stokes respiration, pulmonary edema, and suppression of urine endanger the patient's life, and such temperatures can only be supported for a very few hours at most without proving fatal.

In the article on "Tetanus," in the *American System of Medicine*, vol. i, p. 939, Stewart says that temperatures of 112, 113, and 114° F. (44.4, 45, 45.55° C.) have been recorded.

The type of patient to whom Dr. Smith's communication refers, however, is usually in fairly good general health, and is ready to repeat the temperature phenomenon on the slightest provocation. I have seen a number of such cases where the temperature habit has been very cleverly assumed. The 148° F. (64.4° C.) patient described by a writer in the "Transactions" of the Association of American Physicians (1895, vol. x, p. 159) is an arrant knave and malingerer. I identified him as an old acquaintance, for I turned him out of the Presbyterian Hospital when I found his temperature normal, after I took it myself in the mouth a few minutes after the nurse, in great alarm, had reported it as 109° F. (42.77° C.). He also had "hysterical," or, rather, malingerer's breathing, which disappeared at once when I accused him of being a "fake." Three or four days later I happened to see him in the Surgical Division of the New York Hospital, where trephining him for supposed cerebral abscess had been seriously discussed (!), and where he again exhibited very high thermometric records. He was much surprised and disgusted at being detected again, and I did not have time to urge his dismissal, for he left at once. A member of my house staff identified him also as a patient who had exhibited his "hyperthermy" in one of the Philadelphia hospitals, a year or two before. How he performed his trick, I could not learn, but there was a very definite relation between the height of his temperature and the interest displayed in his case. Anyone who has had playing cards "forced" upon him by a clever prestidigitateur must be able to conceive ways in which the thermometer may be tampered with. It is certainly not done by pressure or friction, for this experiment has been often tried, and without success. It is done by sliding the scale in some manner. It should be borne in mind that the only ready-made thermometers possessing a self-recording "index" are those commonly sold as clinical thermometers, and they usually do not register above 110° F. (43.33° C.) on the scale, with room for 1° or 1½° beyond. The only other thermometers suitable for rectal use which I have been able to purchase ready-made after extensive search are those employed by the beer-brewers, and those made in Europe for thermostats, etc. These thermometers have small bulbs, but large stems; they are without indices, and when tipped a very little below the horizontal line, the mercury can often be made to slide along the scale without application of any other force. On page 182 of the "Transactions," the record of 148° F. (64.4° C.) is given with the significant remark: "Thermometer introduced by patient and removed by nurse." This observation was repeated with the same result (page 183). Many other observations were made by the physicians with the patient "standing up out of bed,"—an admirable position to favor the sliding of the mercury.

When this patient exhibited his 148° F. temperature, his pulse was only 68, but when he had only 112.6° F. (44.47° C. at his disposal, his pulse happened to be 84. His malingerer's breathing fluctuated similarly. When I saw him it was 70, but he could not raise the mercury in the clinical thermometer above named while I kept it vertical and between my own fingers. The character of this patient is exemplified in another statement made in his history, on page 165 (*loc. cit.*), in which he is said to have injured his head in falling from the "walking-beam" of the steamship "Heligoland," plying between Hamburg and New York, in 1892; whereas the facts are that this steamship never had a "walking-beam," and these structures have been out of date upon transatlantic steamers since the days of the "Scotia," many years prior to that time. At the New York Hospital, I found the man had been entertaining the nurses by his exceedingly clever sleight-of-hand tricks—taking oranges from beneath their aprons, and swallowing rolls of bandages and whole bottlesful of medicine, to the consternation of all beholders.

The absurd fluctuations in this man's temperature show how little control he really had over the instrument, for in one of the instances reported (page 180, *loc. cit.*) the record dropped 15.8° F. in five minutes. (The highest temperatures in sunstroke cases cannot be reduced faster than 1° F. in three or four minutes with safety.)

I recall a similar case of a young woman, although with a less ambitious temperature record. This patient's history was reported by Dr. Peabody [1] as a record-breaker. Dr. Peabody spent much time in trying to detect her trick. She appeared afterward at the Presbyterian Hospital, where I identified her and discharged her, after she had been under observation for some weeks and had been examined for possible splenic or subdiaphragmatic abscess. She admitted her deception. She was usually content with a record of 108 to 110° F., but this she maintained at intervals for many months.

There is no doubt whatever that the majority of these so-called "hysterical fever" cases are not hysterical at all in the sense of being in any way controlled by a hypersensitive condition of the heat-centers of the nervous system. An hysterical condition may lead the patient to deceive in this matter, as in many others, but it is safe to assert that all human-body temperatures above 117° F. (47.22° C.) are instantly incompatible with life, and the records of them are only obtained through wilful deception on the part of the patient. There is just one way to prove the genuineness of any such temperature with absolute certainty, and it is so simple that it is remarkable that it is uniformly neglected in such cases. It is to take the temperature of the urine the instant it is voided, with a thermometer which is never allowed to come in contact with the patient's body in any manner. This will give the deep internal body-temperature in the most accurate manner possible. I have often taken the temperature in this manner, and also in women, by passing a long-stemmed thermometer into the bladder, and the record always gives the proper deep internal body-temperature.

In proof of these assertions are innumerable physiological data, as well as the records of clinical experience. The distinguished authority upon physiological chemistry, Halliburton,[2] says: "By fractional heat coagulation, five proteids can be separated in muscle plasma. Four of these are precipitated by various temperatures, and one, of the nature of an albumose, is not precipitable by heat." The three globulins which are thus coagulated by the lowest temperatures are:[3] (1) Paramyosinogen (musculin), which coagulates at 116.6° F. (47° C.); (2) myosinogen, which coagulates at 132.8° F. (56° C.), and (3) myoglobulin, which coagulates at 145.4° F. (63° C.).

A. Sheridan Lea, author of "The Chemical Basis of the Animal Body," in Foster's "Physiology,"[4] gives identical figures.

Kühne [5] also reports an albuminate in muscle that coagulates at 116.6° F. (47° C.)

Landois and Stirling [6] state that "the rapidity of coagulation [in muscle plasma] increases rapidly as the temperature rises, while coagulation takes place very rapidly at 104° F. (40° C.) in cold-blooded animals, or at 118.4 F. to 122° F. (48 to 50° C.) in warm-blooded animals.

I have confirmed this latter observation by experiments upon pigeons, which become rigid and die when their body temperature is artificially raised to this degree.

Speaking of myosin, Foster [7] says: "It is worthy of notice that it coagulates at a comparatively low temperature, *viz.*, at about 132.8° F. (56° C.)."

Turning now to the blood, one finds a similar incompatibility of life with high body temperatures. Halliburton [8] describes cell globulins of the blood, one of which coagulates at 118.4 to 122° F. (48 to 50° C.). Lea [9] says that fibrinogen coagulates at 131 to 132.8° F. (55 to 56° C.) as it occurs in blood plasma, and Halliburton [10] states that "with a solution of fibrinogen and serum-globulin, a temperature of 132.8° F. (56° C.) is employed to precipitate the fibrinogen."

It is thus very evident that with a body-temperature of above 117° F. (47.22° C.), not only would all the muscles be in a state of heat-rigor, and the heart-muscle stiff with coagulation, but some, if not all, of the coagulable proteids of the blood would be coagulated, either making the blood itself semi-solid, or filling it with emboli which would immediately plug all the capillaries. Many of the alleged high body-temperatures reported in medical literature have been insufficiently verified, and have been quoted and requoted without regard to the established simple physiological facts of recent experiment which render it certain that they have had their origin only in clever deceptions practised by the patients. Any such temperature as 148° F. (64.4° C.), or even 122° F. (50° C.), would practically roast the delicate epithelial structures of the body. In a number of experiments which I made some years ago to determine the heat-conveying power of poultices applied to the skin, I found that a temperature in the poultice of 140° F. (60° C.) could scarcely be tolerated, and that for but a short time only. The maximum temperature at which intra-vaginal or rectal injections can be tolerated without discomfort or danger of sloughing should be remembered. A man with a body-temperature of 148° F. would be as stiff as a recent cadaver, and too hot to handle with comfort.

CLINICAL MEMORANDUM.

CONGENITAL ABSENCE OF BOTH PATELLÆ.[1]

BY A. T. BRISTOW, M.D.,
OF BROOKLYN, N. Y.

WHEN my attention was directed to this curious deformity by the following case, I at once made a study of the literature at my command, in the hope of obtaining information regarding it. In the last edition of Quain's "Anatomy," in which special attention is given to anomalies, no mention of the subject was to be found, but a review of the literature of the last few years yielded better results, and I found four similar cases reported.[2] Hartigan gives an account of one case, Körte, quoted by Hartigan, reports two cases, and Railton[3] one. I have also found a number of cases recorded in which one patella was absent, and one curious case in which the patellæ lay in the popliteal space. My case, therefore, as far as I have been able to ascertain, makes the fifth on record of absence of both patellæ.

During the summer of 1895, there came into my service at the Long Island Hospital this child of two and one-half years of age, with a slight pes varus of the right side, and a severe type of the deformity on the left, which evidently called for operative interference. While examining the child for the purpose of correction, my attention was attracted to the case with which a luxation of the knee was produced. Indeed, at first the peculiar crack, with which the dislocation occurred, most unpleasantly suggested a fracture. Closer inspection revealed the fact, however, that the knee-joint on each side immediately became dislocated on bringing the axes of the femur and tibia into line, and that the bones could be displaced in any direction almost at will.

As the joint looked peculiarly prominent, I examined the condyles, and failed to find a patella on either side. The tendon of the quadriceps, instead of being thick and strong, was very thin, and was spread out over the front of the joint, seeming to be attached in part to the condyles of the femur, as well as to the fibula and tibia. There had been no attempt on the part of nature to supply a patella. There have been cases reported where this bone consisted of a rudimentary cartilage, but there was nothing of the sort to be found by palpation in this case.

The most complete account of the cases reported up to this date may be found in Hartigan's article, before referred to. The first case which he mentions was a unilateral defect on the left side, and, curiously enough, most of the unilateral cases seem to have occurred on the left side. In his case the left leg, instead of being flexed by the action of the hamstring-tendon, could not be moved backward after the axis of the leg coincided with that of the femur, but at the child's volition, or with the gentlest pressure, it could be bent forward against the quadriceps, so that the sole of the foot looked upward, with the toes in the groin, in which position the limb was usually maintained. There were two deep creases in the integument anteriorly when the limb was straight, but absolutely no indication of a patella. The writer remarks that the backward displacement of the tibia occurred in uterine life. Other cases referred to are as follows: Chatelain, Neuville, France, 1820, new-born child, left patella absent; Bard, Boston, 1835, absence of patella, dressed with compress under knee, and at three years of age no difference could be noticed in legs; Maas, Berlin, 1874, right patella absent, case did well subsequently; Lane, London, 1858, right patella absent, double pes valgus, subsequent history not given; Labbé, Paris, 1875, child fifteen days old, left patella absent, double pes talus; Caswell, 1865, left patella absent, with malformation of lower limbs; Körte, Germany, 1872, two cases, both patellæ absent; Ammon and Wutzer, 1835, one patella absent.

In all this series of cases there seems to have been an element of spasm, or a contracture of the quadriceps, as it always required more force to bring the limb from its position of extreme anterior flexion backward during the first part of the arc than the last, and much flexion of the

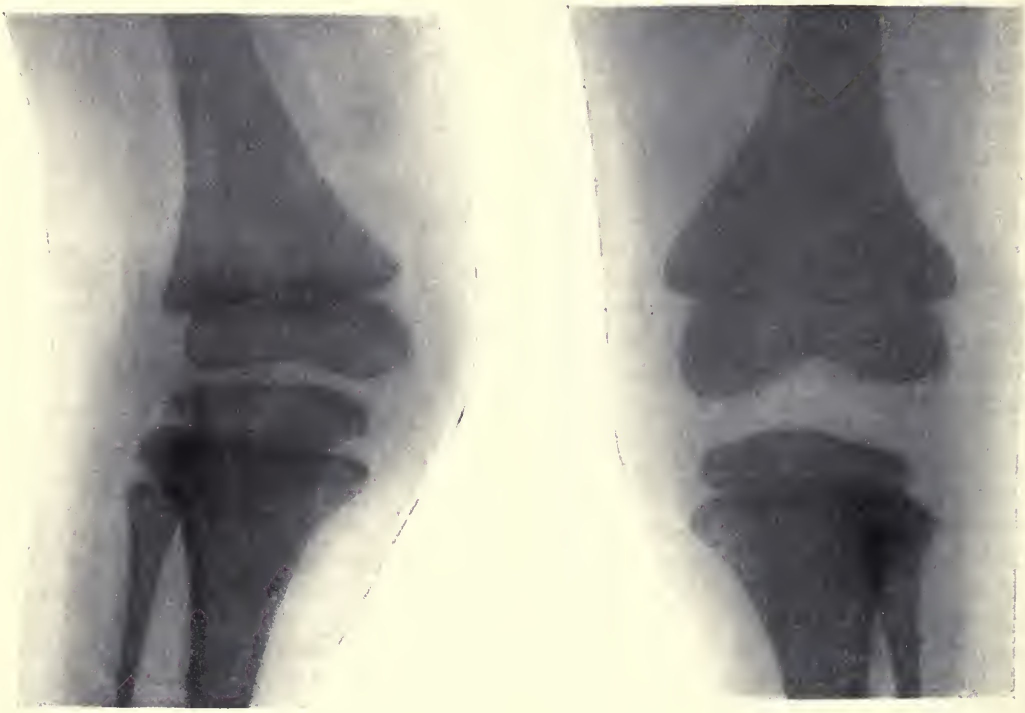
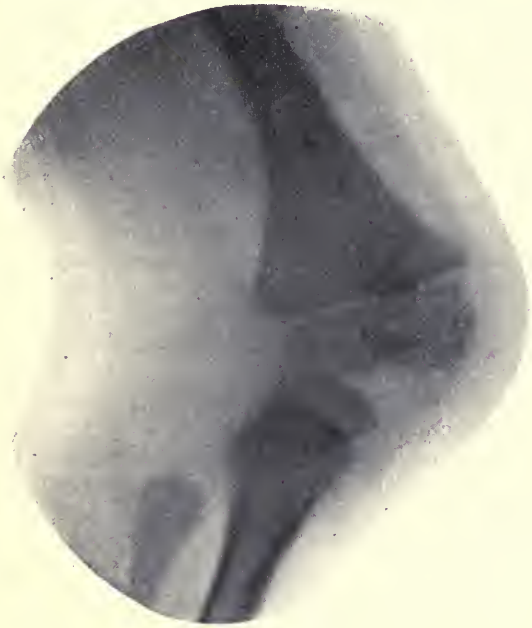
Fig. I.



Right knee-joint. Left knee-joint.

Fig. 2.



Left knee-joint, side view.

limb, or lateral motion, was painful. Bourquet[1] gives an account of a most interesting case, in which the patellæ were not entirely absent, mere vestiges of the bones being found applied to the external condyles. The patient was a man aged twenty-one, who was exempt from military duty on account of a contracture of the right biceps, which did not permit the arm to be extended to more than a right angle. He was a bailiff's officer, for which, indeed, nature evidently intended him, and was in the habit of walking, so the reporter says, from thirty to forty kilometers daily. His lower limbs were very muscular, the thighs shaped like a woman's, with slight genu valgum. He is said to have walked naturally and to have used his legs as if no congenital defect was present. The tendon of the quadriceps was absent, and with regard to the very rudimentary patellæ, the observer remarks that it was impossible to discover them on ordinary palpation. Railton[1] reports a case of congenital absence of both patellæ in a girl of nine months. There was a slight genu valgum on the left side, and a tendency to varus in the left foot. The left hip- and knee-joints, particularly the latter, were so lax that the left foot could be turned around so as to point directly backward. The right knee could not be so treated. The child was otherwise healthy, except for a mild rachitis.

In reviewing these cases, it will be seen that in some there seems to have been a nervous element present as a factor in producing the accompanying peculiar deformity in these patients; but it is possible that this was reflex and in the direction of protecting the joint, for the synovial surface would be most exposed in extreme flexion, and best protected in anterior flexion. All the cases, without exception, seem to have been subject to other developmental errors, a rule to which this case of my own is no exception, as he has a varus of both sides, it being most severe on the right.

---

[1] Bull. et Mem. Soc. de Chir. de Paris, 1885.

[1] Clinical Society of South Manchester, April 26, 1892.

The accompanying skiagrams which very clearly demonstrate the osseous defects, have been procured since the case was reported. I am indebted to Professor W. C. Peckham of the Adelphi College, Brooklyn, for them. They were made with a Thompson focusing tube, and Ruhmkorff coil, eight-inch spark, exposure twenty minutes. Fig. I. shows both extremities, taken on the same negative. The tibia on the right side is dislocated outward and backward with a rotation of the femur inward and tibia outward. The bones are much more closely approximated in this limb than on the left side, as is evidenced by the skiagram. The epiphyseal lines are all clearly seen, the child being three years of age at the time this skiagram was taken. The intercondyloid notch on the left side seems much more marked than on the right, and the profile of the tibial joint-line is more curved.

Plate II. is a side view of the left leg, exposure same as before.

MEDICAL PROGRESS.

A Long Pregnancy.—ROSS reports in the *Australian Med. Gazette*, April 20, 1896, a pregnancy of extraordinary length. On September 30, 1895, the patient, a multipara, thought she detected fetal movements. One week later, October 6, she called upon Ross to have her suspicion of pregnancy confirmed. He felt the movements distinctly at that time, and every week thereafter until the day of delivery, May 20, 1896, *i.e.*, 227 days after he first felt fetal movements. Presuming that they can be felt as early as the end of the third month, it would be necessary to add eighty-four days, making 311 days for the duration of the pregnancy. The condition of the child at delivery coincided with these figures. After a long labor, the os was dilated, the very thick membranes were ruptured, and a female child weighing about nine or ten pounds was delivered with high forceps. Liquor amnii was scanty, and the placenta adherent. The posterior fontanel was completely closed, and the anterior one small and firm, and non-pulsating. The appearance of the child indicated a greater age than 311 days, which is the very shortest conceivable duration of this pregnancy.

Nephritis Due to Hereditary Syphilis.—According to the opinion of AUDEOUD (*Revue Médicale de la Suisse Romande*, August 20, 1896, p. 393) renal alterations may be present from birth in cases of hereditary syphilis, perhaps oftener than is currently believed. The lesion may appear in the form of gummata, of acute parenchymatous nephritis, interstitial nephritis, or amyloid degeneration. These lesions may be manifested during life by the usual symptoms of nephritis-anasarca, albuminuria, anuria, vomiting, and uremic convulsions, and may lead to a fatal termination. It is important to recognize early the etiology of the cases, in order to institute appropriate treatment promptly and effect a permanent cure.

Hepatocele in a New-born Infant, with a Successful Operation.—PATRY (*Revue Médicale de la Suisse Romande*, 1896, No. 7, p. 354) has reported the case of a new-born infant of well-formed parents, who presented in the median line of the abdomen, between the ensiform cartilage and the symphysis pubis, a roundish, slightly bosselated tumor of pinkish tint, about as large as an orange, and sharply circumscribed in outline. The mass was covered by thin, semitransparent membrane, continuous at the periphery with the umbilical cord, which arose from the lower portion of the tumor. Upon palpation, the prominence was resistant, and not fluctuating, and appeared of homogeneous consistence; it yielded a dull note on percussion. The mass was readily reducible, but returned when the taxis was removed. The usual area of hepatic percussion-dullness was wanting. The condition was recognized as one of defective closure of the abdominal walls, with ectopia of the liver. A radical operation was proposed and undertaken on the third day, with ultimate success. Jaundice, lasting for six days, developed, and a small hernial protrusion remained. The latter manifested itself only when the child cried or coughed, and was easily controlled by means of a bandage.

The Influence of Fever Upon Metabolism and Upon Thermogenesis.—As the outcome of an experimental study of the influence of fever upon intra-organic chemic changes, and upon thermogenesis, KAUFMANN (*Compt. rend. hebd. des Séances de la Soc. de Biologie*, 1896, No. 25, p. 773) has determined that the febrile state is attended with an increase in the respiratory interchange, in the excretion of urea, and in thermogenesis. In the febrile starving animal the intra-organic chemic phenomena are simply exaggerated, but they are not modified in their nature. The respiratory coefficient remains nearly normal, and the production of heat in excess is about proportional to the excess of oxygen absorbed. The totality of heat generated may be related to simple oxidation-processes, as a result of which albumin and fat are transformed into sugar, and sugar into carbonic-acid and water. According to results already obtained, the rectal temperature and thermogenesis do not display the same modifications. As a result, the thermometer may not furnish an exact index of intra-organic chemic activity, or of the production of heat during fever. During the febrile state, thermogenesis is increased more in the liver than elsewhere. This fact is in accord with previous observations upon febrile rabbits with differential thermometry.

Hypodermic Injections of Serum in Cholera Infantum.—The *Gazette Hebdomadaire de Medicine et de Chirurgie* quotes Reinach of Munich, as having had a successful result in the therapy above indicated. Reinach had fifteen cases of cholera infantum in which he employed subcutaneous injections of cow's serum in doses of from 10 to 20 cubic centimeters. Four of the patients died; two had a concomitant broncho-pneumonia, and two had a follicular gastro-enteritis of long standing. The effect of the injections manifested itself ordinarily in from six to eight hours after the administration of serum, and from that time the temperature gradually rose, the extremities became warm, the cyanosis gave place to a rosy tint of the skin, and the diarrhea was arrested. This condition generally continued on the following day, and recovery usually occurred after one injection only. In some cases, however, a second injection was necessary in order to maintain the good results which were obtained by the first one. Besides these injections, rice water was given. The author states that, from a nutritive point of view, twenty cubic centimeters of assimilable serum are equivalent to five ounces of cow's milk, or to an ounce and a half of the mother's milk.

Muscular Wry-neck.—KADER has had opportunity to study thirty-four cases of muscular wry-neck, and the results of that study, as published in the *Beiträge z. klin. Chir.*, vol. xvii, p. 207, form an instructive chapter in our still imperfect knowledge of this peculiar disease. In twenty-one cases the sterno-mastoid muscle was removed and microscopically examined. From these investigations, Kader concludes:

1. In muscular wry-neck, there exists an interstitial fibrous myositis of the sterno-mastoid muscle.
2. This myositis consists in excessive growth of the connective tissue of the muscle and degeneration of the muscular parenchyma, its place being taken by newly formed connective tissue, so that not only is the stroma thickened, but large patches are found which are partially or wholly connective tissue.
3. The myositis may affect the whole muscle or only a part of it.
4. The myositis has a chronic, progressive course, although its onset is marked by a more acute character.
5. The transformation of the newly formed granulation-tissue into old cicatricial tissue produces the contraction-atrophy and rigidity of the sterno-mastoid.
6. Other muscles besides the sterno-mastoid may be affected. If so, the same process takes place in them.
7. The alterations sometimes observed in the nerves are secondary to those of the muscles, and are to be looked upon as caused by the extension to the nerves of the inflammation going on in the muscle.

THERAPEUTIC NOTES.

Intestinal Antisepsis.—BOUCHARD recommends the following combination in cases of gastric and intestinal putrefaction, the diarrhea of typhoid, in poisoning by foods, and in dysentery:

℞ Finely pulv. β. naphthol . 15 grm. (ʒ iii, gr. xlv.)
Salicylate of bismuth . 7 grm. 50. (ʒ i, gr. l.)
Divide into thirty powders. S. from 3 to 10 a day.

Nocturnal Incontinence cured by Massage.—In the *Gazette Medicale de Paris*, October 17, 1896, BESTCHINSKY of Russia speaks of the efficacy of massage in nocturnal incontinence of urine, as follows:

The patient empties his bladder, then the bowels are well moved by means of an injection; he is then placed on his back, the legs flexed. The physician then puts his index-finger in the rectum and applies it obliquely against the neck of the bladder, thus producing a slight massage in the direction of the pubes. The other hand is applied externally against the finger already in the rectum, in order that too great a pressure may not be made on the rectal wall. In this manner the massage is kept up for two or three minutes, then the patient reposes a little, after which the massage is resumed. One *seance* a day of from five to eight minutes' duration is enough.

In the cases so treated by Bestchinsky the incontinence diminished after ten *seances;* instead of appearing every night, it was reduced to twice a week, and after twenty applications the incontinence ceased entirely. The author recommends this treatment only in those cases where incontinence is the one symptom. Organic affections producing incontinence are a contra-indication, as are those cases where incontinence is purely a local symptom. The same author also cites an instance where music acted as a valuable therapeutic agent in the treatment of a similar case.

On the Manner of Employing Resorcin in Cutaneous Affections.—HARTZELL gives the following formulas for the use of resorcin in dermatology (*Rev. gén. d. Ther.*, November 8, 1896). In subacute moist eczema a two-per-cent. watery solution of resorcin is alone often sufficient to cure. Its sedative action is, however, increased by the addition of common salt. Thus:

℞	Resorcin	4 parts
	Sodium chlorid	1 part
	Distilled water	200 parts

In erythematous eczema a three-per-cent. watery solution of resorcin, to which glycerin is added (ten drops to the ounce of solution), if lightly applied to the inflamed area several times a day will give relief.

In weeping eczema the following formula is indicated:

℞	Resorcin	1 part
	Dermatol	3 parts
	Glycerin	1 part
	Lime water	50 parts

If the skin is dry a resorcinated paste may be made of:

℞	Resorcin	1 part
	Starch powder	8 parts
	Oxid of zinc	8 parts
	Vaselin	15 parts

In chronic squamous eczema resorcin is not of much use.

In ulcers of the leg, an ointment containing resorcin, two grains to the ounce, is soothing and stimulates granulation.

On account of its lack of color and odor it is especially adapted for use upon the scalp:

℞	Resorcin	1 part
	Alcohol	50 parts
	Vaselin	150 parts

The above ointment is to be rubbed into the scalp at night, and is to be used in cases of seborrhea, daily at first, and then on alternate days.

Under the influence of a plaster containing resorcin, rodent ulcer of the face may completely heal. Such a plaster should contain:

℞	Resorcin	3 parts
	White wax	4 parts
	Powdered resin	4 parts
	Olive oil	q. s.

THE MEDICAL NEWS.
A WEEKLY JOURNAL
OF MEDICAL SCIENCE.

COMMUNICATIONS are invited from all parts of the world. Original articles contributed *exclusively* to THE MEDICAL NEWS will after publication be liberally paid for (accounts being rendered quarterly), or 250 reprints will be furnished instead of payment. When necessary to elucidate the text, illustrations will be engraved from drawings or photographs furnished by the author.

Address the Editor: J. RIDDLE GOFFE, M.D.,
NO. 111 FIFTH AVENUE (corner of 18th St.), NEW YORK.

Subscription Price, including postage in U. S. and Canada.

PER ANNUM IN ADVANCE	$4.00
SINGLE COPIES	.10
WITH THE AMERICAN JOURNAL OF THE MEDICAL SCIENCES, PER ANNUM	7.50

Subscriptions may begin at any date. The safest mode of remittance is by bank check or postal money order, drawn to the order of the undersigned. When neither is accessible, remittances may be made, at the risk of the publishers, by forwarding in *registered* letters.

SATURDAY, JANUARY 2, 1897.

ALBUMINURIA AS AN EARLY SIGN OF TUBERCULOSIS.

WITHIN the last few years, several clinical observers have claimed that in the early stages of tuberculosis, particularly when the disease involved the lungs, albumin could be found in the urine, and that in obscure cases in which the diagnosis of tubercular infection was doubtful, a urinary examination should be made, with the object of determining whether this additional diagnostic evidence was present. Quite recently Tiessier delivered a lecture in which he endorsed this view and expressed the belief that in these cases the albuminuria depends in no way upon a nephritis, and that it is usually met with in young persons, especially of the male sex. Curiously enough, he went still further, and claimed that it is found only in cases of hereditary tuberculosis, or, to speak more correctly, in those who have a strong predisposition to the development of this malady. In discussing the importance of this symptom and the possibility of its occurrence as a diagnostic factor of value, Saundby asserts his belief that the albuminuria is simply that which is seen so frequently in cases of profound debility, and that as most cases of tuberculosis of a hereditary type are instances of profound debility, the albuminuria has no particular significance.

With this opinion we are inclined to agree, the more so as there seems to be reasonable doubt as to whether the so-called albuminuria of tuberculosis is really an albuminuria, or the albumosuria to which attention has recently been particularly called by Harris of Chicago. This condition is by no means infrequent in nearly all infectious processes, notably in tuberculosis, croupous pneumonia, the various other infectious diseases, and conditions associated with streptococcus-infection: in other words, the albumosuria or albuminuria, whichever it may be, is simply a manifestation of the infection of an individual by some microörganism; and while it is indicative of the development of an infection, it is not indicative of any one particular disease. Whatever, therefore, may be the ultimate value of this symptom in reaching a diagnosis in suspected cases of tuberculosis, at present it cannot be relied upon to any considerable extent.

Further than this, the fact that in the presence of suspected infection no albuminuria is found to be present does not even exclude the possibility of an infection, for in many such cases a careful microscopic examination of the urine, the sediment of which has been obtained by means of the centrifuge, will reveal casts of all forms, although careful chemic examination fails to reveal any albumin whatever. Thus Kössler, in a recent paper quoted by Saundby in the *Birmingham Medical Review*, found all kinds of casts in twenty-nine cases in which no albuminuria existed, although the greater number of the patients were suffering from an acute infective disease.

On the other hand, the presence of casts, according to Kössler, is not to be given too great pathologic significance, for he asserts that subsequent *post-mortem* examinations of the kidneys of some of these patients showed no structural evidences of nephritis whatever. In other words, the value of the urinary examination in cases of infection depends not only upon the finding of casts or albumin, but upon their association.

The well-recognized fact that a diagnosis cannot be made from a single symptom, but only from a number of associated symptoms, is once more emphasized.

A REVOLT AGAINST THE LODGE.

THE physicians of Santa Clara county, California, 124 in number, have associated themselves together and pledged themselves to do no contract work for lodges or other organizations at reduced rates. They estimate that heretofore lodge members have obtained medical service at the rate of about fifteen cents on the dollar.

The action taken by the Santa Clara physicians is in every way commendable, and is worthy of wide imitation. A similar organization should exist in every lodge-ridden community of the civilized world; but it is doubtful if such spirited enthusiasm and unanimity could be aroused in any other section of our broad land. Cliques and factions, combined with selfishness and competition, so distract most medical bodies that, even in the case of most crying evils, unanimous action is well-nigh unknown.

Lodge and other contract medical work is acknowledged by all thinking men to be degrading and demoralizing to both recipient and giver, and like the indiscriminate, gratuitous medical services of dispensaries tends toward the pauperization of both. There is no difference in the two conditions. Medical service given at less than its real value is charity, whether the recipient looks upon it so or not; and charity, unworthily bestowed, begets an unnatural dependence which is on the border of pauperism.

Fully fifty per cent. of the people pay their bills only because they have to, and doctor's bills come in for their full share of procrastination and neglect. The fallacious idea that physicians earn their fees easily incites this debt-shirking class to any and every expedient to get medical advice and treatment for nothing, or next to nothing. This is the sole cause of the fattening of dispensaries and clinics, and the prime *raison d'être* of the lodge. Tenaciously rooted as this conspiracy is, and appealing as it does to the self-interest and base ambitions of a few disloyal physicians, it has come to stay, in our larger communities at least.

For a time the 10,000 residents of Santa Clara Valley must pay regular rates for medical services according to their means. But in all probability it will be for a time only that the sovereign people of this sunlit vale will submit to such presumption on the part of their doctors, for it is safe to predict that before the three years of the pledge expire, the lodges will have all the medical attendants they want. Struggling outside physicians will see in this state of siege a possible, although unenviable, chance for establishment, and will jump not only the county bounds but also the "Standing Committee," appointed to interview newcomers, and, to our shame be it said, some of the signers of this pledge, because of an imaginary or real need, weakness or cupidity, may backslide and join the foe.

There is one remedy, and only one, for these and kindred ills of the medical profession—a remedy neglected because apparently unattainable. We like to flatter ourselves that we belong to a noble and benevolent profession, and may we never forget it; but the sooner we convince ourselves that medical services are, within certain limits, subject to the same law of supply and demand as the trades or manual labor, or even ordinary commodities, the sooner we can apply the remedy. When the crop is light, grain is high; when the crop is bountiful, grain is low and perhaps is fed to hogs, or even used as fuel.

The present annual crop of doctors is certainly bountiful; what wonder then that fees are lowered, lodge and contract tyranny submitted to, and sometimes euthanasia sought as a relief from overcrowding and competition.

For these and most other ills of this kind the doctor has himself to thank; but it is not yet too late for us, by unanimous uprising, to curtail the output of medical colleges, or, better still, to shut up or consolidate about half of them. Many of them exist largely from selfish motives, and it necessarily transpires that many of their graduates are not infused with a high or lasting professional ideal.

What wonder then that some will sell their services cheaply to lodges, some descend to arrant quackery, and others, still, drift into abortion and other lawless practices!

Each physician of Santa Clara Valley must get his living from 565 of population, and therein lies the rub. It is time for him, and every thinking physician, to bestir himself and discourage young men, unless especially fit, from entering the medical profession by telling them truthfully how always laborious and generally unremunerative a physician's life is.

ECHOES AND NEWS.

Lunacy in London.—The number of insane in the city of London is reported to be above 13,000, with an average increase of more than 600 each year.

Jenner Memorial.—A public movement is on foot in London to raise funds to establish some institution in connection with the British Institute of Preventive Medicine as a memorial to Jenner.

The Cullingworth Fund.—The subscription to the fund to reimburse Dr. Cullingworth for the expense he incurred in defending himself in the recent suit for damages are already sufficient to meet the expenditure and no more will be received.

A New French Hospital in Constantinople.—About one hundred years ago a French hospital was founded in Constantinople. It has recently been rebuilt in accordance with the modern idea of sanitation and asepsis, and was formally opened on December 12, 1896.

The King Humbert Hospital.—After three years being occupied in its erection, the Royal Hospital at Monza, Italy, has been formally opened by King Humbert, whose name it bears. It will accommodate nearly three hundred patients and in the detail of its appointments is thoroughly modern and unusually complete.

Valuable Goods in Small Packages.—A Mrs. Donaldson of Camden, N. J., recently gave birth to a perfectly-formed, healthy child which weighed but seven and one-half ounces. Its head could be contained in an ordinary teacup, and its hand covered by a silver 25-cent piece. At last accounts it bade fair to thrive.

Beriberi in Dublin.—The epidemic continues. In all, 113 persons have been attacked. Of these seven have died. The marked symptoms in the majority of the cases are weakened heart action, paresis of the leg muscles, and localized anesthetic patches. A tendency to relapse is a marked feature of the epidemic.

Filmogen.—At the Medical Club of Vienna, Schiff recently described an agent for covering denuded cuticle under the name of Filmogen. This is a solution of nitrous cellulose in aceton, combined with an oleaginous base. It forms a yellowish semi-fluid body, insoluble in water, flexible when dry, and causes no pain to the denuded surface.

Lumbar Puncture in Plumbic Encephalopathy.—Dr. Seegelken, assistant to the Medical Clinic at Jena reports a case of coma due to lead poisoning in which the patient's life was saved by lumbar puncture. About two ounces (60 grams) of cerebro-spinal fluid were withdrawn, after which the patient promptly recovered consciousness, and all symptoms disappeared within thirty-six hours.

The Delirium of Talk.—The *British Medical Journal* directs attention to this prevalent affection. It is said to present its most dangerous phases in the inflammatory oratory of the present day. No class seems wholly free from its influence, while the highest pitch of destructive fury is found among politicians. It is cautiously suggested that the clergy are not unknown among its victims, and even doctors are not wholly excluded.

Meeting of the Western Ophthalmological Association.—The Western Ophthalmological, Otological, Laryngological and Rhinological Association, of which Dr. Adolf Alt of St. Louis, is president, and Dr. Hal Foster of Kansas City, Mo., is secretary, will hold its annual meeting in St. Louis on the second Thursday and Friday of April, 1897. Physicians desiring to read papers are invited to send subjects to the secretary at once. Programs of the proceedings will be issued early in February.

Poison in Cosmetics.—At a recent meeting of hairdressers in Paris, it was stated that the rice-powder, sold largely to ladies as a cosmetic, was by no means so harmless as its name indicated, but contained varying proportions of white lead, chalk-starch, and alabaster. Many years ago, owing to the chemical investigation of the face-powders at that time popular with American ladies, this evil was in a great measure corrected, but it is not at all improbable that it is again a source of danger in America as well as in France.

Hygienic Examination of Schools.—The Board of Health of New York City has received an appropriation of $47,500 for the establishment of a special corps of medical inspectors, whose duty it will be to look after the health of all the children attending the public and parochial schools, and to exercise a supervision over the sanitary conditions of all the school buildings under the jurisdiction of the Board of Education. The system, which will be introduced at the beginning of the year, is already in vogue in London, Paris, and Boston, and has met with encouraging success.

Charges against Dr. E. J. Tucker.—Dr. E. J. Tucker, chief of the medical staff on Randall's Island has been charged with general inefficiency and lack of medical experience, and it is probable that he will shortly be summoned before the Commissioners of Charities and Correction to refute the charges. It is said that he owes his appointment to political influence, that he is a dentist by profession, and that he has not written a medical prescription since assuming the duties of the position. Dr. Tucker claims that the charges have been instigated by a discharged nurse, and that they have no foundation in fact.

Intestinal Absorption and Excretion.—Herr Hoinjmann has recently made some interesting observations in the case of a woman, who, in the healing of an abdominal abscess, had the misfortune to have the colon completely excluded from participation in the process of digestion. The chyme was discharged from a fistula involving the latter part of the ileum. Only four per cent. of fats were discharged, showing that they are absorbed by the upper intestinal surface. Albumin, however, escaped in considerable quantity, as was also true of iron when administered, showing that the colon plays an important part in their assimilation.

The Oyster and Disease.—On December 5th, Dr. Thorne delivered a lecture before the National Health Society in London upon "Oyster-culture in Relation to Disease." In this he stated that the oyster had been definitely proven to be a carrier of the specific microbes of cholera and enteric fever, and in at least one instance the bacillus coli had been found inside the mollusk. It was conclusively shown, he thought, that great danger attended the consumption of oysters fattened in waters contaminated by these and kindred germs, and in future a guarantee to the effect that their beds were free from pollution should be demanded of those engaged in oyster-culture.

Quack-medicine Manslaughter in Dublin.—A most distressing fatality occurred in Dublin ten days ago by which a young clergyman lost his life. It was shown at the inquest that he had suffered from neuralgia, and one of those busybody friends who abound everywhere, undertook to cure him by a nostrum which some one told him that some other person had heard was efficacious in some one else's case. Having procured this stuff he gave it to the servant girl without instruction, written or verbal, as to its use, and she left it on the supper tray where the victim found it and swallowed it, dying within a few minutes from poisoning by the aconite which it contained. In this transaction there is nothing but the familiar elements of the average patient who is stupidly willing to swallow any nostrum that an equally stupid and ignorant friend extols.—*Med. Press and Circ.*

Fire at the New York Polyclinic.—A disastrous fire, which had its origin in an adjoining building, completely gutted the fourth floor of the New York Polyclinic Medical School and Hospital, early on the morning of December 25th last, and placed in imminent danger the lives of some sixty-five patients, all of whom, however, by the active efforts of the nurses, physicians, and members of the police, were removed in safety. The number included some twenty or more children from the orthopedic wards, and several upon whom laparotomy had been performed on the immediately preceding days. No untoward effects of their hasty removal into the bitterly cold air have resulted. The faculty of the Polyclinic immediately arranged for roomy temporary quarters a short distance from the site of the fire, and the regular order of clinics and lectures was resumed before the large class of students on the 30th ultimo.

Twelfth International Medical Congress.—Claudius H. Mastin, M.D. of Mobile, Ala., has been requested, and has consented to serve as one of the members of the American National Committee of the Twelfth International Medical Congress, to be held at Moscow, August 19–26, 1897. The Central (Moscow) Executive Committee consists of the following gentlemen:—President, Professor I. F. Klein; Vice-President, Professor A. J. Kojewnikow; Secretary-General, Professor W. K. Roth; Treasurer, Professor N. F. Filatow; Secretaries, Professor P. I. Diakonow, Professor A. J. Tikhomirow, Professor I. I. Neyding; Members, Professor S. S. Korsakow, Professor J. F. Ognew, Professor W. D. Cherwinsky. It is officially announced that preparations are being made for the reduction of Transatlantic steamer and European railroad fares. A. Jacobi, M.D. of New York, is the Chairman of the American National Committee.

One Solitary Medical College in North Carolina.—Mr. S. P. Stafford, of the class of 1897, medical department, University of Pennsylvania, calls attention to the fact that an error occurs in a recent editorial which appeared in the NEWS in connection with the statement that there is not a single medical school within the confines of the state of North Carolina. He speaks most highly of the Leonard Medical College, located at Raleigh, N. C., and also volunteers the information that it was organized in 1882, that it has a corps of ten professors, and that from sixty to seventy-five students are graduated yearly. While the correction is cheerfully made, and acknowledgments tendered to our correspondent, it is to be regretted that North Carolina must descend from the proud pedestal upon which our imagination had placed her. A city, to say nothing of a State, without half a dozen actively working schools of medicine annually turning out scores of young practitioners to battle unsuccessfully against the dispensary evil, is a *rara avis* deserving of our highest admiration and respect!

Surgeon-General Robert Adair.—The hero of that fine ballad "Robin Adair," was a dashing young Irish surgeon, who, about the middle of the last century, finding his way into London society, was fortunate enough to secure the affections of Lady Caroline Keppel, daughter of William, second Earl of Albemarle, and his wife, Lady Anne Lennox, daughter of Charles, first Duke of Richmond. The match was naturally looked on with disfavor by the family of the young lady, and it was during a period of temporary separation that Lady Caroline is said to have written the words of "Robin Adair," and set them to the old Irish tune of "Eileen Aroon," which she had learned from her lover. At length, however, love triumphed, and the pair were united on February 22, 1758. Within a few days Adair was appointed inspector-general of military hospitals, and, subsequently, becoming a favorite of the king, was made surgeon-general, king's sergeant-surgeon, and surgeon of Chelsea Hospital. He died in 1790.—*Notes and Queries.*

CORRESPONDENCE.

THE FUROR SCRIBENDI.

To the Editor of the MEDICAL NEWS:

DEAR SIR: Your little editorial, "The Furor Scribendi," no doubt stirred a responsive chord in the bosom of many a reader. Are we poor folks to be considered merely a passive machine, a sort of many-mouthed, but voiceless hopper, into which is to be cast a lot of offal? As a matter of fact, the thing is getting unbearable, and I seriously think of taking "arms against a sea of troubles and, by opposing, end them." It must be delightful for the one possessed of the furor scribendi to count off and contemplate in advance the number of blows he can inflict on his poor, suffering, passive victim. For example: I go to a meeting of our State Medical Society and hear a paper read; the paper is good or indifferent, as the case may be. The paper, with its fellows, and the discussion thereon, is printed in the Transactions, bound in a volume, and eventually finds a place on my shelves. So far, so good; no harm is done. I can take up the volume at an idle moment, go over its pages, and feel a thrill run up and down my back whenever my eyes rest on my own name and that of some colleague whose paper I trailed in the dust. Or I can indefinitely dispense with the electric shock, and allow the Transactions to rest and get covered with dust and cobwebs. But I little know the man possessed of a furor scribendi. When the society meeting has fairly retired to some Rumpel-kammer within my skull, I get a reprint (compliments of the writer, Mr. Editor), and that meeting is hauled out from its retirement. A glance at the reprint does the work; I am very impressionable, and surely it would be sacrilege to throw my friend's reprint into the waste-basket without a glance.

After the reprints from the Transactions are exhausted I breathe easy for a while, and regain a feeling of security. But that crowd, Mr. Editor, is sly—devilish sly. All unprepared and innocent, I am jumped upon by all of them at once, and am made to pay for the privilege, too! Upon a preconcerted signal, they invade my medical journals, and I am buried under a mass of that stuff which I have twice shoveled aside. The cold sweat stands in beads on my brow; I sink back speechless, if not exhausted, nearly, if not quite, knocked out. I know they have yet another arrow, another string to their bow—the reprints from the medical press.

Now, if those possessed would give us an inkling when and where the casting-out process is to take place, and would confine themselves to one place and time, we might evade them; as matters are, there is no escape. Like the bacteria, the possessed are ubiquitous, and are fighting "with daggers of lath." I am resigned; I am prepared "rather to bear those ills we have than fly to others that we know not of."

Very truly,

ALFRED F. FUCHS, M.D.

P. S.—Send me reprints! Shall I not have my pound of flesh?

LOYAL, CLARK CO., WIS.
December 19, 1896.

OUR PHILADELPHIA LETTER.

[From our Special Correspondent.]

ORGANIZATION OF THE PHILADELPHIA PEDIATRIC SOCIETY.—MEETING OF THE COUNTY SOCIETY.—A UNIFORM STANDARD OF MEDICAL EDUCATION.—INFLUENCE OF PREGNANCY ON IDIOPATHIC EPILEPSY.—APPENDICITIS.—CHOLECYSTOTOMY.

PHILADELPHIA, December 26, 1896.

In response to a call issued recently about 125 physicians assembled on the evening of December 22d at the College of Physicians to form what is now known as The Philadelphia Pediatric Society. The meeting was duly called to order, and the following officers were elected to serve for the ensuing year: Dr. J. P. Crozer Griffith, president; Dr. E. E. Graham, Dr. A. V. Meigs, and Dr. Frederick A. Packard, vice-presidents; Dr. Alfred Hand, jr., secretary; Dr. C. F. Pettibone, treasurer; Dr. Charles W. Burr, Dr. William B. Atkinson, Dr. Alfred Stengel, Dr. Thompson S. Westcott, and Dr. William C. Hollopeter, executive committee. A Constitution with By-Laws was then adopted, and the second Tuesday of each month appointed as the time for meeting. The objects of the Society, briefly stated, are the exhibition of cases, the verbal or written reports of cases of interest, the exhibition of pathological specimens bearing upon pediatrics, and the presentation of special papers, or the holding of pre-arranged discussions of special subjects,

At a stated meeting of the Philadelphia County Medical Society, held December 23d, the following papers were read and discussed: Dr. Silas Updegrave supplementing a paper read by him May 13, 1896, treated at length of "A Uniform Standard of Medical Education for the Degree of Doctor of Medicine." His suggestions were somewhat radical, and time alone will reveal their practicability. The subject of an exhaustive research by Dr. F. Savary Pearce was "The Protean Influence of Pregnancy on Idiopathic Epilepsy." After consulting the records of a number of hospitals, private institutions, and obtaining a case here and there in private practice, he had compiled a series of some twenty cases illustrating his subject. As a rule the findings were that during pregnancy the seizures, either of *petit mal* or of major epilepsy, were lessened in frequency and violence. One of the cases quoted by Dr. Pearce brought to light a rather peculiar and interesting point. A woman throughout her pregnancy, which had progressed well into the latter half, had had numerous generalized attacks of *grand mal*, lasting for several hours. Labor pains now came on, and the attending physician on examination found a mal-presentation. Version was done with a view of expediting delivery. The pains of labor ceased, however, and the woman went on to full term without the recurrence of a single epileptic seizure. An attempt to explain the total cessation of these attacks after versions involves one as deeply as does the making of a satisfactory hypothesis as to the cause of so-called idiopathic epilepsy, which is itself, as one of the numbers present aptly expressed it, an hypothesis to everyone save the man who has it.

D. Mordecai Price reported a number of interesting cases in abdominal surgery. Speaking of the diagnosis of appendicitis, he divided the signs into two classes, one of which pointed correctly toward the affection named, and the other group, which he called "symptomatic," indicated rather impaction. He said were he called, in consultation, to a case with or without the obtainable history of abdominal injury or overindulgence in eating, a mass suddenly appearing in the right iliac fossa having no tendency to enlarge, pain localized in that area, a temperature of 1, 2, or 3°, his judgment would incline rather to the symptomatic group, and he should advise free purgation, rather than operation. Citing a number of cases to prove his point, he went on to say that he considered the *early* appearance of a lump in these cases rather as a sign of good omen than the opposite. Increase in the size of the mass, a chill, a temperature normal, or below that point, with a pinched expression about a face already anxious, would incline him to the belief that pus was present and that operation was indicated at once. Absolute freedom from fear in the establishment and maintenance of free drainage is essential to success in such cases. Of operations on the gall-bladder, he reviewed a number of cases—one particularly interesting because of its peculiar and tragic termination. A large woman, sixty-five years of age, had had periods of acute suffering covering twenty years, When he was called to see her, he found her jaundiced or, rather, bronzed to a depth of color that only the hypothesis of malignancy complicating impaction could satisfy. Acute, intense pain in the right shoulder and elbow was complained of. Upon operating, he found the gall-bladder enormously distended, out of position, containing large stones almost four inches in length. Several of these were easily removed, the last and longest with the greatest difficulty, after exerting extreme caution. The edges of the gall-bladder were then stitched to the abdominal wall, free drainage established, and the case progressed favorably until the fourth day, when the woman was unexpectedly found dead in bed, deluged with blood. Exploration revealed the fact that one of the large stones had, with its sharp facets, sawed through the abdominal aorta, so weakening it as to cause it to rupture under the circumstances mentioned.

OUR PARIS LETTER.

[From our Special Correspondent.]

THE UNIVERSITY OF PARIS ORGANIZED—FOREIGN DOCTORS IN FRANCE—OPPORTUNITIES OFFERED BY THE PARIS CLINICS—ALCOHOLISM IN FRANCE—JEAN CHARCOT, M.D., MARRIES MME. JEANNE HUGO, ETC.

PARIS, December 1, 1896.

During these last few days decorators have been lettering the various buildings of the medical school with the words: "University of Paris." The legend is the external manifestation of the vital internal development that has led to the union of all the teaching faculties in Paris under one governing body. It was formally acknowledged at the Sorbonne on November 19th, when, in the presence of all the faculties of the university, of all the high officials of France—civil, military, and naval, of the representatives of all the foreign governments, and of all the members of the various academies ('the immortals'), the President of the Republic, inaugurated the University of Paris. The independent examining boards created by Napoleon I. in 1808 have gradually acquired the powers of faculties, and being drawn together by mutual interests, have gained solidarity in their evolution, and this formal inauguration is not a new creation but a legal adoption of the existing state of affairs by the Republican Government.

The law that formulated the new state of affairs has its interest for foreign medical students. Hereafter no foreigner will receive the degree of Doctor of Medicine unless he expresses his intention of practising outside of France. Moreover, as the applications for service in the hospitals, an important part of the medical training for two or three years of the course here, are already too numerous, no foreigner will be granted the privilege of being an interne in Paris, though I believe they may still be received as such by the other faculties of France.

This practically closes the door against foreigners for undergraduate medical studies. The impression has somehow got abroad that this influences the position of those who wish to do post-graduate work, but this seems absolutely without foundation. American doctors particularly, if I may judge from my own experience, and know it is not exceptional, are heartily welcomed. Privileges are accorded for the asking that would be unthought of in America. Doctors may hear all lectures and attend all clinics, accompany any physician or surgeon in his visit to his wards, and take a number of special courses simply on the presentation of some formal evidence to the Dean that he is a regular graduate. He may follow all the ordinary practical courses—dissection, physiology, bacteriology, pathological anatomy, etc., on the payment of one fee—forty francs (less than $8). Besides he may if he shows an interest in certain specialties have the opportunity to see all the clinical material in such immense institutions as *La Salpetriere Becêtre*, for nervous diseases; *St. Louis*, syphilis; or *L'Asile Ste. Anne*, mental diseases. After a while one almost gets the feeling that it is an imposition on good nature, so cordially do the great French clinicians put themselves at one's service. There is but one objection, and that is the distance one has to travel for material. Taking the medical school as a center, *La Salpetriere*, *St. Louis*, *Ste. Anne*, and the Pasteur Institute, are at the ends of four about equidistant radii, and each two miles at least away from the school.

The new University of Paris begins with about 26,000 students, having gained 10,000 students in ten years, about the same rate of increase as at the University of Pennsylvania (considered wonderful with us), only what the latter has gained in hundreds Paris has gained in thousands. Of these, 5144 are medical students, a decrease of over 300 from last year, attributed by the Dean, who officially announced the attendance November 26th, to the regulations regarding foreigners. At present the number of foreign undergraduates is about 900.

There is just now considerable interest in the question of alcoholism here in France, and a decided effort is being made to secure the passage of sumptuary and revenue regulations to regulate the evil. The discussion has brought out very clearly one important fact. It has been the custom to say that the evils usually attributed to alcohol (disease, degeneration, insanity) were not due so much to the amount of the alcohol consumed as to the quality of it. As is often said in America, it is the fusel oil, the paraldehydes, the higher alcohols, and certain poisonous ethers contained in poor whisky that makes its ravages so serious among the poor. Repeated chemical analyses at the Sorbonne of series of liquors selected for the purpose show that these substances are present in quantities so small that practically they may be entirely neglected in the results produced. Joffroy of *L'Asile Ste. Anne*, has published a series of experiments to the same effect, from a biological standpoint. It takes no more of the poorest alcohol obtainable to kill an animal than it does of the very best. The vile-smelling, bad-tasting, often ill-looking alcohol that comes over at the very beginning, or again near the end, of the distillation of a quantity of liquor will kill an animal, when injected, no sooner than the bland, oily alcohol, with its pleasant "bouquet," that comes over in the very heart of the distillation. The experiments have been repeated often enough to give the assurance that the conclusion is correct.

The whirligig of time and one of the freaks of the little love-god have brought about a marriage that has attracted a good deal of attention in medical circles here and in England. Jean Charcot, M.D., the son of the famous Charcot of *La Salpetriere*, married last week Mme. Jeanne Hugo, the granddaughter of Victor Hugo. Mme. Hugo is the divorced wife of M. Leon Daudet, the son of Alphonse Daudet, the writer. It was after his marriage with Mme. Hugo that Leon Daudet wrote his infamous book, "*Les Morticoles*," a satire that is intensely bitter on the medical profession of Paris. He had studied medicine for five years, had failed three times in his examinations for interne of the hospitals, and then took this means of avenging his failure. His father's name, and the love of the Parisians for anything new, especially when it is abusive of existing institutions, gave the book a vogue that it is hard for an American to understand, for it is in a way the recapitulation in a grossly exaggerated form of everything hard that has been said against the medical profession from the beginning.

December 8th.

The sudden death has just been announced of Professsor Strauss, who has occupied the chair of experimental and comparative pathology in the medical school of the University here. Professor Strauss was only fifty-one years of age, and his death comes as a great shock to his colleagues in the faculty. He was one of the men who gathered around Pasteur when that great master was doing his wonderful experimental work and who, having imbibed his teaching and learned his methods, have been able to carry on his work. His observations on glanders, with Roux and Nocard at Alexandria, and with Roux at Marseilles on cholera at the time of the last epidemic, brought him prominently forward. Of late years his experimental work with regard to the contagiousness and heredity of tuberculosis, attracted world-wide attention. His experiments with Gamaleia on the relations between human and avian tuberculosis did a great deal to bring into relief that important and vexed question. Only last year he published his book of one thousand odd pages on "Tuberculosis and its Bacillus." which is the best and most complete study of the subject to date. In 1888 he succeeded to Vulpian's chair in the faculty of Paris. While Vulpian had taught experimental medicine mainly from a physiological standpoint, Strauss saw the direction in which modern scientific medicine was drifting and at once practically made the chair one of bacteriology.

On the first Monday in December of each year, Pinard at the Baudelocque Clinic of Obstetrics, invites all the patients on whom he has performed symphyseotomy to return for examination before the class. It is the best possible demonstration of the after-effects of the operation as regards locomotion, etc. He then gives his statistics for the past year, and any changes in the indications for operation or any modifications of the technic he has seen fit to adopt. So far, Pinard has performed 82 symphyseotomies, with a mortality of 9 mothers and 12 children. None of the mothers died directly from the operation, but usually from some intercurrent disease due to the protracted labor. They are often in labor for days before being brought to the clinic. The children were born dead in all but 4 of the fatal cases, and death was usually due to the same causes as those present in the mothers. During this past year he has operated 14 times, with 2 maternal and no infantile deaths. One of the mothers died on the sixth day from lobar pneumonia, the pneumococcus being found after section; the other died from septicemia. In twelve instances he has done symphyseotomy more than once on the same person. Union of the symphysis has always taken place, and none of the functions of the pelvic joints have been disturbed.

As regards indications for the operation, no changes are to be noted except that as time goes on nature is trusted more and more in contracted pelves, and spontaneous deliveries are patiently awaited. Out of 95 contracted pelves at the clinic during the year, 68 were delivered spontaneously, and in but 14 was symphyseotomy needed. As to technic, the points special to Pinard seem to be: "Never open the symphysis more than 7 cm., not from fear of injury to the sacro-iliac synchondroses, but because it will cause injurious tension on the soft parts. In primaparæ always dilate the vagina with a water-bag before delivering. In extreme contraction version is indicated. No bony sutures are necessary, and if used they may lead to suppuration."

Three of Pinard's great maxims are prominently displayed on a large tablet in his clinic room:

"Embryotomy on a living child is a thing of the past."

"No pregnancy should ever be interrupted prematurely. Infants delivered this way, as a rule, either die within a few days or live, miserable weaklings in mind or body."

"The child has the right to its mother's milk."

Last year at the Baudelocque, there were 2100 labors, with a mortality from all causes of less than one-half per cent.

Last week I was present at a demonstration on the part of the students, who were resolved not to listen to the lectures of one of the assistant professors. Professor Farabœuf is ill, and after some delay Assistant Professor Sebileau was chosen to give the lectures on anatomy in his stead during this semester. Dr. Sebileau has rendered himself obnoxious to the students by the rigor of his examinations, and by having opposed several student-movements last year. His opening sentences were greeted with catcalls, cheers, stamping, and general confusion. Every time he tried to begin his lecture the same performance was repeated. Finally, after twenty minutes' effort to be heard, he sent word to the dean.

Professor Brouardel (the dean), who seems to be quite popular, received a very cordial welcome. He was listened to attentively while he explained that the lectures on anatomy would have to go on. Then he sat down, and Dr. Sebileau attempted to talk, but it was of no use; the crowd at the back of the immense amphitheater and in the doorway would not allow him to be heard. The dean once more interfered and was listened to, but they would have none of Dr. Sebileau. Finally, the dean announced that if the lectures on anatomy were not given this semester there would be no examination in the subject this year. This brought the crowd to its senses, and any attempts at disturbance thereafter were promptly put down by the students themselves, and the lecture proceeded more or less peacefully. Time is precious to the Parisian medical student, and the loss of a half year would be a serious thing. At twenty-six he must have his degree, or else serve his full three years as a soldier like the rest of mankind in France. He is exempted from two years of military service, but on the condition that he be either a practising physician or an interne of one of the hospitals before he is twenty-seven. When between the ages of nineteen and twenty-seven, a young man has to devote one year to military service and five years to medical studies, the missing of an examination means a good deal.

Some recent reports to the Academy of Medicine, to the Society of Biology, and the Hospital's Union seem to show that the injection of artificial serum (normal salt solution) may prove as useful to the physician as it has to the surgeon. It has been tried with excellent results in the gastro-enteritis of children where this is accompanied by exhaustive diarrhea or rapid collapse; in a word, in the choleriform conditions. It has been used in animals in poisoning cases, especially in poisoning by strychnin, with encouraging results. In both classes of cases, the indications that it meets seem to be the depression of nerve-force and the consequent defective elimination. The increased blood pressure seems to lend tone to nerve centers, and hasten elimination this way and mechanically, besides diluting materially toxic substances that are present.

A modification of this artificial serum-therapy has been reported as giving good results in the infectious fevers. It has been tried particularly in pneumonia and typhoid fever. The patient is bled several times in the early stages of the disease, and each time the amount of blood taken is replaced by normal salt solution. Toxins are thus effectively disposed of, yet without materially weakening the patient. The remedy would seem to have a field for usefulness in such states as uremia, chronic and acute lead poisoning, and diabetic coma; in a word, in any condition where symptoms are the result of the presence of toxic elements in the circulatory system.

Foreign Doctors Excluded.—Italy is trying to conform to the illiberal precedent of her French and Swiss sisters, and to impose prohibitive conditions on practitioners of non-Italian qualifications.

Paris.

PROLAPSE OF THE RECTUM.—SUTURE OF INTESTINAL PERFORATION DUE TO TYPHOID FEVER.—CURE FOR VOMITING IN PHTHISIS.—SALINE INJECTIONS.

AT the Société de Chirurgie, November 11, 1896, BAZY presented a woman upon whom he had performed an *operation for prolapse of the rectum* nearly three years previously. The prolapse formed a mass measuring 18 by 14 cm., and it was reduced and stitched by five sutures to the coccyx by the method first described some years ago by Gérard-Marchant. Recovery was complete, and there had been no relapse, although pregnancy and a miscarriage at the seventh or eighth month had since occurred.

GERARD-MARCHANT, who was present, mentioned other cases in which the results of this operation—recto-coccypexy—had satisfactorily stood the test of time. The more recently devised colopexy in which an attempt is made to hold up the rectum by stitching it to the sigmoid flexure has not been in use long enough to test its merit.

At the session of November 18, 1896, the subject was still further discussed, and NELATON stated that colopexy was only to be recommended in severe cases where other measures failed. A patient upon whom he had performed this operation died on the sixth day of septic peritonitis.

WALTHER described a *congenital cyst of the neck*, which was still small at six months, but when the child was a year old it had grown so as to seriously compress the vessels. Aspiration of its contents—serous fluid—gave immediate relief, but the cyst rapidly refilled. Such cysts ought to be removed entirely. Even if they are intimately associated with the blood-vessels, their attachment is usually such a slight one that the cyst wall can be peeled off without difficulty. An exception has to be made in favor of mediastinal prolongations, if such exist.

The *suture of perforations of the intestine occurring in typhoid fever* was recently discussed before the Académie de Médicine by MONOD. By further search through medical literature he found a total of 32 operated cases, with 5 recoveries. In 3 of these the record was not as complete as it should be. The other 2 recoveries were absolutely certain, and granting that every perforation occurring in typhoid fever is fatal, even this small percentage of recovery is sufficient to justify operation in every case in which the general condition of the patient will permit it.

In an operation of this kind performed by ROUTIER upon a patient eight or nine days sick with typhoid fever, the surgeon had no guide to the localization of the perforation other than the pain localized in the right iliac fossa. He found and sutured two perforations and left the peritoneal cavity open, draining it with gauze. Unfortunately, death followed in eleven days from new perforations occurring in the neighborhood of the sutured ones.

Further observations upon this subject were made at the session of November 25, 1896, when BRUN reported a case occurring in a boy of fourteen years who, during a relapse after typhoid, and one month after he first entered the hospital, presented suddenly all the signs of acute perforation. On the following day, although septic peritonitis was well established, Brun opened the abdomen from the umbilicus to the pubis, found the perforation, sutured it, flushed the abdominal cavity with four quarts of boiled water, and closed the wound over gauze drains. Thanks to injections of serum the patient made a slight gain, but on the third day fecal matter appeared along the drains, and death followed on the seventh day after operation. The sutured perforation was in good condition, but there were five other perforations, and in the wall of the small intestine there was a considerable area, completely necrotic.

LEJARS has twice operated for typhoid perforation. In both instances with a fatal result. One of these failures was the more discouraging, in that the operation was performed in about sixteen hours, the perforation was easily found and quickly closed. The patient left the table in good condition, but died on the third day. No other perforations were found at autopsy, and the death was attributed to the typhoid fever itself.

At the session of the Société de Thérapeutique, held November 25, 1896, **MATHIEN** described his treatment for the *vomiting of food in phthisis* when occasioned by a persistent hacking cough. Attempts to control the cough and so prevent the vomiting by giving opiates, or by means of blisters and the cautery, have not been successful. The trouble lies with the too sensitive mucous membrane of the stomach. Mathien first gave his patients bits of ice to swallow after eating. This was successful in preventing the cough. Later he made use of chloroform water, one-half saturated, and menthol. Two to four teaspoonsful of the chloroform water and ¼ to ⅓ of a grain of menthol, taken immediately after eating, has relieved this cough in his patients and prevented the vomiting.

FERRAND looked upon these attacks of vomiting after meals as reflex and often due to an excessive sensibility of the pharynx. In such cases he has practised with success the repeated application to the pharynx of a solution in glycerin of bromid of potassium, ten per cent. or even twenty per cent. This application should be made before meals, The effect is to diminish the sensibility of the pharynx and cause the vomiting to disappear.

At the Société de Biologie, November 28, 1896, **ROGER** explained the experiments he had undertaken to determine whether intravenous injections of saline solutions really do produce a *lavage of the blood* as has been claimed. They increase diuresis, but it does not necessarily follow that poisons in the body are thereby eliminated. To determine this point, Roger injected small quantities of cyanid of potassium into the veins of several rabbits. A part of the animals then received into their veins 100 to 160 c.cm. of saline solution. The presence of the cyanid in the urine was shown by a blue color upon addition of ferric chlorid. The reaction was obtained in the control rabbits in thirteen minutes, while in those which had received the saline solution it was evident in seven minutes. Further, it disappeared from the urine of these rabbits in three hours and forty-five minutes, but lasted in the urine of the control rabbits four hours and a half.

Experiments with the indigo sulphate of soda gave similar results, and on account of the staining of mucous membranes and skin which follows the intravenous injection of this substance, the action of the saline injections could be followed with the eye. The blue tint disappeared more rapidly in those animals which received saline injection than it did in the control animals, so that the skin and mucous membranes of the former had resumed their normal color, while those of the latter were quite blue.

One is safe, therefore, in saying that the saline injection really does cause a lavage of the blood, or more correctly, a lavage of all the tissues of the body.

The clinical testimony to the action of *saline injections in infants* was brought out in the Société médicale des Hôpitaux, November 27, 1896, by **BARBIER**, who has treated a number of nursing infants suffering from intestinal infections, by subcutaneous injections of a sterilized solution, 7–1000. The injections were made under the skin of the sides of the abdomen, and did not exceed 15 c.cm. twice a day. Following the injections there was observed a stimulation of the whole organism, apparently the result of increased blood pressure and an elevation of temperature.

In general the injections are not indicated in acute infectious enteritis with fever, or in chronic enteritis marked by fever and progressive wasting. The injections did not have any action on the diarrhea, nor upon the other symptoms except the collapse, and there did not seem to be any real beneficial effect upon nutrition.

COMBY thought that saline injections were to be classed with caffein and ether. They provoke a more or less active stimulation of the body, but usually only a temporary one.

HAGERN considered saline injections one of the most powerful of sthenic remedies. Looking upon them in this light, they were seen to be indicated in conditions resembling that of cholera, but probably would be found to be useless in gastro-intestinal dyspepsia.

Vienna.

RESECTION OF THE TRACHEA.—OSTEOMALACIA.

In the session of the Medical Society held November 13, 1896, **FÖDERL** presented a six-year-old boy upon whom he had performed *resection of the trachea* with circular suture. The child's trachea had been cut entirely through just below the cricoid cartilage. The posterior wall had been sutured immediately, and five days later the rest of its circumference was sutured except where a canula was kept in place. There was so much contraction in the scar that phonation was completely lost and symptoms of stenosis developed. Föderl performed tracheotomy low down, resected the scar tissue to the extent of 2½ cm., and brought the ends together by a circular suture. The result was perfect.

In the Vienna Medical Club, November 11, 1896, **HERTZ** presented two patients suffering from *osteomalacia*. One of them was a shoemaker whose back for twelve years had been growing more bent. For a short time he had noticed redness and swelling in certain finger-joints. Examination showed that rotation and anterior flexion of the head was impossible, owing to synostosis between the occiput and atlas. There was marked kyphosis. The pelvis presented the characteristic prominent symphysis seen in osteomalacia.

The swelling of the joints disappeared promptly after the administration of salicic acid. Hertz was therefore of the opinion that the affection of the joints was rheumatic in its nature, and that the case was therefore either a combination of osteomalacia and rheumatism, or else that the whole process was rheumatic.

Latzko considered this an undoubted case of osteomalacia, which he said often began with joint affections. Moreover, the fact that the patient was a man was nothing against the diagnosis. He had seen four cases of this disease in the male. He advocated the use of large doses of phosphorus, although they occasionally caused periostitis.

Kassiowitz believed that it is possible to secure the same effects with small doses of phosphorus. Even with children no symptoms of poisoning ought to follow its use.

Singer thought the case presented was one of arthritis deformans, a disease which has many points of resemblance with osteomalacia, especially with the so-called senile form of the latter. He also called attention to the fact that pes valgus is often an early symptom of osteomalacia.

Braun was able to observe the motion of the heart in a case of extensive resection of the ribs. The apex of the heart does not move downward, outward, and to the left in systole, but upward and to the right. At the same time the base of the heart moves downward. The contraction of the left ventricle is very rapid like a flash, that of the right is a gradual, wavy motion accompanied by a similar motion of the pericardium.

SOCIETY PROCEEDINGS.

NEW YORK ACADEMY OF MEDICINE.

General Meeting December 3, 1896.

Joseph D. Bryant, M.D., President.

THE MANAGEMENT OF PNEUMONIA.

S. Baruch, M.D., read a paper with this title. (See page 1.).

DISCUSSION.

Dr. Charles B. Folsom of Boston opened the discussion. He said that at the Boston City Hospital he had tested the cold-bath treatment in thirty-six cases of pneumonia, all of a severe type. The method consists in placing the patient in a sheet, and rubbing him with a towel and water at a temperature varying from 70° to 95° F., for about ten minutes. The patient is then wrapped in a blanket and allowed to rest for half an hour. Of these thirty-six cases, eight died, a mortality of 22.2 per cent. The mortality in that hospital for croupous pneumonia averaged about thirty-five per cent. Of the fatal cases, one had typhoid fever, one had pleurisy, three were victims of chronic alcoholism, one had general diplococcus infection, as shown by the presence of endocarditis, pericarditis, and cerebral meningitis; one had chronic nephritis, and one had phthisis. As death was only hastened by an intercurrent pneumonia in the case of phthisis, the patient dying on the thirty-first day, and as the case of chronic nephritis was fatal on the second day, these might fairly be excluded. If this were done, the mortality would be 17.6 per cent. He had been convinced from the observation of these cases that the cold baths were very effective, and he was more than satisfied with the results. In marked contrast with the bath treatment of typhoid fever was the fact that all these patients said that the baths were grateful to them. In conclusion, he would say that these baths controlled the fever, diminished the cough, lessened dilirium, and induced sleep.

Dr. E. G. Janeway said that his experience had led him to dread the afebrile pneumonias of old people more than the highly febrile pneumonias of the young. In the former, neither cold baths or cool compresses had any place; all our efforts must be directed to sustaining the failing strength of the patient. These cases were exceedingly fatal notwithstanding the comparative absence of symptoms. We must look at pneumonia in several different aspects, and must take into consideration, not only the toxemia and the inflammation of the lung, but the individual reaction. Although the prognosis was necessarily very grave in cases in which as much as three lobes were involved, he had seen a number of these cases recover, and in these the treatment had consisted chiefly in the use of oxygen, alcohol, and the so-called cardiac stimulants. Oxygen was of special value when the breathing capacity was markedly diminished, and we could not afford to overlook this fact even though we called pneumonia an infectious disease. Heart stimulants might be required, either early or late, in this disease, and when such a contingency arises as edema of the sound lung, cardiac stimulants must be given hypodermically. He thought the cold compresses made the patients about as comfortable as any other measure, yet he was bound to admit that he had seen a number of pneumonia patients do very well with nothing but a flannel shirt. He was not one of those who believed in decrying the coal-tar series of drugs, simply because a number of physicians, following more particularly the example of the Germans, had observed bad results from their use in unnecessarily large doses. When administered judiciously in proper cases and in moderate doses, they would be found to be of very great value. For example, he had very recently seen a severe case of pneumonia with a temperature of 106° F. The patient had had but little sleep, was slightly delirious, and had a rapid pulse. In this case he had recommended giving five grains of phenacetin, and repeating it, if necessary, in two hours. As a result of this the temperature remained low for about six hours, and the patient slept well that night. True, the temperature rose the next day to about 105° F., but the next night a dose of six grains of phenacetin was sufficient to secure another good night, and after this the temperature remained low, and the patient made an uninterrupted recovery. He mentioned this case because cold applications had been used to no purpose, while phenacetin had accomplished the desired result. Morphin might have done the same thing, but it would probably have also caused constipation and disturbance of the liver. Our rule in the use of these particular drugs, as with all others, should be to give the smallest dose which will accomplish the desired result. Much had been said about the responsibility of aborting pneumonia. Years ago he had been skeptical about the possibility of calomel doing this, as had been claimed, but since then he had occasionally observed cases which seemed to prove that this might sometimes occur. It was, however, decidedly exceptional. It was right and proper to make an effort to abort the disease, and hence if we saw a case in the chill stage, we should direct that the patient's feet should be kept in a warm bath for half an hour, and that he should be given hot drinks, sweet spirits of niter, liquor ammonii acetatis, and aconite, and subsequently, a large dose of quinin.

Dr. W. P. Northrup referred to a case in which he firmly believed that by the use of similar measures at the onset of the first symptoms he had succeeded in preventing the development of a genuine pneumonia. He said that he too had met with many cases of afebrile pneumonia in old people; but he was unable to say much about their treatment, as they had invariably proved fatal. In all cases of pneumonia he was particular about securing an abundant supply of fresh air to the sick room, if necessary, by keeping the patient near an open window. He had not the slightest fear of these patients catching cold so long as the feet were kept warm, and there was a high fever. He also gave oxygen in pneumonia, but usually, as he had said, by way of the window. He had learned from Dr. Baruch that a bath of 90° F. would often calm a very excitable patient with an alcoholic pneumonia, and would at the same time improve his general condition. He had proved by experience the benefits of hydrotherapy in pneumonia, and believed that in this disease the effect of such treatment could be briefly summed up by saying that it quieted the mental excitement, improved the quality of the pulse, increased the depth of the respirations, and promoted sleep.

Dr. Alfred Meyer said that he had tried the effect of the "digitalis treatment" of pneumonia in his service at Mt. Sinai Hospital, with the result that only two out of twelve patients died. According to the author of this treatment, the daily dose of the drug should be as high as 60 to 120 grains of the digitalis leaves.

Dr. Baruch, in closing the discussion, said that he had not observed any of these cases of pneumonia occurring in old age without fever, and with but few other symptoms. He could not subscribe to the recommendation of oxygen gas, for it seemed to him that according to the law of the diffusion of gases it could not be taken into the system in any quantity. He, however, approved very highly of the principle of this treatment, and made it a point to supply the patient with as much oxygen as he could absorb by giving him an abundant supply of fresh air. He approved of the use of digitalis as a heart stimulant in the early stage of pneumonia, but in the later stages, when the heart was working hard to overcome the contraction of the peripheral blood vessels arising from the action of the toxins, the administration of digitalis did not meet with his approval; it seemed too much like spurring on a jaded horse. The failure of the cold applications in the case in which Dr. Janeway had found phenacetin so efficacious could in all probability be explained by the manner in which they had been made. As he had said in his paper, everything depended upon the exact manner in which the cold compresses were used. It was for this reason, he believed, that the profession had been so long in recognizing the great value of this method of treating pneumonia.

MEETING OF THE NORTHWESTERN MEDICAL SOCIETY.

October 21, 1896.

Frederick Peterson, M.D., read a paper entitled

MUSICAL AND ARITHMETICAL PRODIGIES AND COURT-FOOLS.

He said that the term "idiots avants" is applied to all such idiots, imbeciles, or feeble-minded as exhibit special aptitudes of one kind or another, always out of proportion to their intellectual developments in other directions, and often remarkable as compared with similar developments or faculties in normal individuals. He spoke of the many cases of this kind recorded in the literature, and of those who are exhibited as musical prodigies, calculating boys, and the like in the museum.

Precocity and an extraordinary power of the faculty of mental arithmetic have been frequently noted in idiots. This faculty consists entirely of excessive powers in simple calculation, and is observed only in the congenital variety of idiots, imbeciles, and degenerates. In idiots, in whom the musical faculty is well developed in contrast to the general intellectual paucity, it is not of a high order. It consists of a remarkable auditory memory, together with a power of expression by means of the vocal musculature or fingers of the musical memory stored up in the brain. There is no spontaneous musical expression, no power of invention.

Examples of idiots avants with talents bespeaking disproportionate development of the visual centers, together with the power of reproduction by modeling, drawing, or painting, are occasionally to be met with.

Among idiots, imbeciles, and feeble-minded it is not uncommon to meet cases with an aptitude for drollery, and given to witty or humorous remarks and actions. The court-fools of Shakespeare are the types of this class of degenerates. Any quick-witted imbecile or feeble-minded individual in ancient times had no difficulty in securing a good livelihood, and sometimes even prosperity and fame. Under such conditions it became common for normal individuals to adopt the calling of the jester or buffoon, and these were known as artificial fools. The reader summarized in the following:

The idiots avants are mere copyists in music, modeling, designing, or painting. Yet at the same time their talents stand out in strong contrast to their general feeblemindedness. As a rule the aptitudes are precociously developed, and are frequently lost before reaching adult life. The physical basis of such talents must be a precocious perfection of the cerebral organization in certain areas, together with a true hyperplasia of tissue in such regions, and a tendency to early degeneration. There must be an increased number of cellular elements and sensorimotor combinations and associations in definite parts of the brain. Cases of misplaced aggregations of such tissues in the brain have been described under the name of heterotopia of gray matter, and it is possible that some such unequal distribution of the structures underlying psychological processes will be found to account for the presence of the extraordinary talents of idiots avants.

Dr. Fruitnight thought that the intellectual possessions of these degenerates were confined exclusively to the imitative faculty.

Dr. Newman said that if we could have *post-mortems* and careful histological study of some of these cases, it would be of great interest in going to establish the anatomical substratum of their possessions and defections.

Dr. Bulkley asked if the reader of the paper had given any consideration to the theory propounded by Hudson, particularly in regard to the subjective and the objective mind. He thought it worthy of consideration by physicians, especially in the explanation of faith-cures, hypnotism, and the phenomena of love.

Dr. Burchard mentioned an opportunity which he had had to observe the case of an idiotic girl who evinced remarkable mathematical power, on whom Charcot made some of his first experiments in hypnotism. She could add, multiply, and divide with astounding rapidity and accuracy, and perform the most perplexing tasks in mental arithmetic, yet she was a typical idiot in almost all other respects.

Professor Pupin of Columbia University said that when lines of social divisions were much more strictly drawn than they are to-day, it was those of the inferior caste who devoted themselves to music, and not the masters. Among the Slavs and Italians, and some others of the Latin race, there are found many who excel in particular things, and especially in the productiveness of their emotional side, but often such excellence is associated with a lack of proper balance or interrelationship of all their mental possessions. On the other hand, the Anglo-Saxon race possessed this desirable balance of mind to an exceptional degree; in fact, that is their distinguishing characteristic.

Dr. H. L. Taylor alluded to the fact that advanced educators aimed to ascertain the special aptitudes of their pupils, in order to use them as centers for the coördination of studies, and as a basis for introducing the child's mind to related topics. He asked if the special aptitudes of the defective might not be similarly used, so that deficient parts of the mind might be educated by means of the proficient.

Dr. Peterson, in closing the discussion, said that he had collected as many cases from the literature as he could find to call the attention of pathologists to the subject. Precocity was a condition that was of interest in considering the subject of idiots avants, as the two are perhaps somewhat allied. The contentions of Hudson he believed to be speculative, without justifiable premises. There certainly exist many cases of absolute idiocy. Any faculty that defective children have well developed, be it visual, auditory, or other, should be developed, because through it, later, the necessary associative faculties may be developed.

He thought that music was a sensual, not an intellectual art. Intellectual men take up pursuits that are engrossing, and music remains for them an indulgence. Those of inferior possessions may be unfit for such pursuits, and music may be for them an occupation, and a very absorbing occupation.

In the time of court-fools, those who were odd in body as well as in mind were selected for this office, and if they were not fools by nature, they sought to become fools by artifice, because of the profitable nature of the calling. Any physical deformity, such as ugliness, dwarfishness, kyphosis, clubfoot, etc., was always of genuine advantage to the artificial fool.

Professor Pupin of Columbia University exhibited a "focus tube" containing two electrodes, the cathode one concave, the other flat and made of platinum. The electric discharge starts from the source of the X-ray, and the focus becomes the point of radiation. By this means the intensity of the ray is increased perhaps a hundred fold. Increase in the intensity of the ray is due to the employment of a platinum disk. To contribute to the intensity, all the gas must be absorbed, and the tube must represent as nearly a perfect vacuum as possible. If the proper vacuum is obtained, and the electric current has a proper intensity, then the platinum disk on which the cathode rays are focussed glows in a small point, which is brought to a white heat, while the remainder of the platinum is only at a dull-red heat. The space inside should be kept at a definite temperature. This is done by heating the tube with a Bunsen burner or a spirit lamp; or, what is still more convenient and reliable, a small platinum-wire helix is placed inside the tube surrounding the glass tube which carries the cathode. This wire is connected to a storage battery, and the heat thus produced will regulate the temperature of the vacuum-tube.

The second device relates to the regulation of the current, and is as follows: Connect one of the electrodes of the vacuum-tube to a brass screw, and regulate properly the length of the air-gap between this screw and one of the poles of the induction-coil.

The speaker also exhibited a skiagram of a fourteen-year-old boy's spinal column, the result of a ten minutes' exposure, and remarked that as the use of the X-ray became more and more perfected the time of exposure was lessened.

The X-ray has many of the peculiarities of many other luminous rays, especially in regard to its being selectively absorbed by substances. It is in this direction that the possibility of differentiating the various internal tissues of animal bodies must be sought.

REVIEWS.

A MANUAL OF PHARMACOLOGY AND THERAPEUTICS. By WILLIAM MURRELL, M.D., F.R.C.P., Physician to and Lecturer on Pharmacology and Therapeutics at the Westminster Hospital, etc. Revised by FREDERICK A. CASTLE, M.D., Member of the Committee for Revision and Publication of the U. S. P., etc. New York: William Wood & Co., 1896.

THE American edition has been considerably changed from the original English form, not only with regard to the necessary alteration of official preparations, but by the introduction of much new matter in the sections on Climate and Natural Mineral Waters, credit being given to Dr. Arthur H. Nichols of Boston, and to Dr. George E. Walton of Cincinnati, respectively. The volume consists of 516 neatly printed pages, without illustrations. The introductory part of 140 pages discusses ancient remedies, sources, and adulterations of drugs, idiosyncrasy, habit, cumulation, incompatibility, etc., and such non-medicinal methods of therapeusis as venesection, transfusion, electrotherapy, "cures" of various kinds, diet, exercise, etc. Under the head of palatable prescripting, the author regrets the paucity of the vehicles of the British Pharmacopœia. In "The Art of Prescribing," it seems to us that the author has been influenced too strongly by antiquated conceptions. We find no evidence of the principle of giving one thing at a time, and with reference to a definite physiological action. The work is avowedly a student's text-book, yet the author starts with a cough-mixture of morphin and chloroform, which is allowable only in the most exceptional cases. Illustrative of the treatment of dyspepsia—which kind is not stated—we find a mixture of sodium bicarbonate, chloroform and gentian, whose only claim to respectability is its age. Again, we note an acid combination of quinin to be given before meals. The formula of an "excellent purgative pill" is given as follows: Calomel gr. iij, extract of hyoscyamus—enough to make a pill. The American reviser very mildly remarks that "when there is daily need for a peristaltic persuader, calomel is not altogether desirable;" we would add that the propriety of treating extract of hyoscyamus as a mere vehicle, to be used at the pharmacists' discretion, is questionable. We hardly know whether to praise or blame the author for omitting all reference to Latin in prescribing. There follow sections devoted to inorganic subjects, synthetical compounds, vegetable, and animal drugs. One of the most useful parts of the volume is a few pages giving lists of drugs in pharmacological groups. The classification makes no pretense to completeness, and is all the more useful for being clinical rather than strictly scientific. For example, one wishing a diaphoretic has a choice of muscarin, picrotoxin (*sic*), Dover's powder, and several others; "mouth-dryers," producers of glycosuria, vesical, and urethral alteratives, and other therapeutic groups are listed. A number of formulæ are appended, some of which are excellent, others simply time-honored. In the index is included the maximum single adult dose of each drug. On the whole, we are forced to the verdict that the volume does more credit to the publishers than to the author, and we hope it is not national pride that leads us to say that the work can in no way rival the standard text-books of Wood, Shoemaker, Hare, and other American authors.

TWENTIETH CENTURY PRACTICE. An International Encyclopedia of Modern Medical Science. By Leading Authorities of Europe and America. Edited by THOMAS L. STEDMAN, M.D. In Twenty Volumes. Vol. viii: Diseases of the Digestive Organs. 8vo., pp. 667. New York: Wm. Wood & Co. 1896.

This, the eighth volume of the Twentieth Century Practice, represents the work of eight contributors, by whom the subjects have been treated as follows: Diseases of the Mouth, by Johann Mikulicz and Werner Kümmel; Diseases of the Esophagus, by Reginald H. Fitz; Diseases of the Stomach, by Max Einhorn; Diseases of the Pancreas, by H. Leo; Diseases of the Peritoneum, by E. Farquhar Curtis; Animal Parasites and the Diseases Caused by Them, by J. Ch. Huber; Treatment of the Diseases Caused by Animal Parasites, by Jas. M. French. As may be seen, the several articles have been mostly written by those especially competent to write upon their respective subjects. The individual contributions are comprehensive, without being redundant, and they represent the most recent views, both pathologic and clinical. The volume altogether maintains the reputation established by its predecessors in the series, and stands upon the high plane aimed at by editor and publishers. It would have been a natural arrangement to follow Diseases of the Stomach by Diseases of the Intestines, then both by Animal Parasites, and finally to group Diseases of the Liver, Diseases of the Pancreas, and Diseases of the Peritoneum together, but we can understand that circumstances beyond immediate control should have necessitated modifications of such a plan. The article on Diseases of the Peritoneum includes a consideration of the subject of appendicitis, as well as of peritonitis, due to perforation of stomach or bowel, and of subphrenic abscess. Although rather a pathologic than a clinical manifestation, abdominal fat-necrosis is so often found associated with disease of or about the pancreas that it would seem to be deserving of notice in a Practice of Medicine.

AN AMERICAN TEXT-BOOK OF APPLIED THERAPEUTICS. For the Use of Practitioners and Students. Edited by J. C. WILSON, M.D., Professor of the Practice of Medicine and of Clinical Medicine in the Jefferson Medical College, Philadelphia, etc., assisted by AUGUSTUS A. ESHNER, M.D., Professor of Clinical Medicine in the Philadelphia Polyclinic, etc. W. B. Saunders, Philadelphia. 1896.

This bulky volume of 1326 pages embodies the contributions of the two editors and over forty collaborators, many of them distinguished specialists, teachers, and investigators. Only two of the contributions are from foreign pens—that on malaria, by Professor Laverau of Paris, and that on leprosy, by the late Dr. Beaven Rake, Medical Superintendent of the Trinidad Leper Asylum. The work is essentially one on treatment, as its name, "Applied Therapeutics," implies, and is an amplification, by skilled writers of similar chapters found in some text-books on therapeutics.

The subjects have been arranged, so far as possible, upon modern pathologic doctrines, and include most diseases and pathologic processes, as well as a consideration of the disorders of pregnancy. Purely surgical procedures have been omitted.

The articles are well illustrated, when necessary; that on diseases of the mind, by Dr. John B. Chapin, particularly so.

To those who prefer their theory and practice of medicine dismembered, as it were, this book will prove very acceptable; but there are those still among us who cling with fondness to old tomes in which the same master-hand wrote on all branches pertaining to his art.

That specialism has rendered this impossible is partly true and wholly lamentable, for we need carry the same idea on but a few steps and foresee the time when this extreme subdivision of work will invade practice as it has literature; and the already much-tossed-about-and-torn patient, having the etiology, pathology, diagnosis, and prognosis of his disease determined by four separate men, will then be handed on to a fifth for treatment. Whether specialists in euthanasia will then arise to administer permanent relief, time alone will tell.

There is really very little to criticize in the book. Many will not agree with one author that mercuric chlorid is a wise disinfectant for typhoid stools and privy vaults, but this little slip is more than compensated for by the author's loyal advocacy of the bath in the treatment of enteric fever.

It is a pleasure also to note the faith Dr. Danforth has in blood-letting in croupous pneumonia.

Altogether, the work is admirable, up to date, practical, and not too controversial.

A TEXT-BOOK OF HISTOLOGY. Descriptive and Practical, for the Use of Students. By ARTHUR CLARKSON, M.B., C.M., Edin. W. B. Saunders, Philadelphia. 1896.

The aim of the writer of this work on histology has been to furnish the student in one volume of 554 pages, with both the descriptive and practical parts of the science. With this aim two chapters are devoted to the consideration of general histologic methods, and then the different tissues are taken up in fifteen subsequent chapters.

In each chapter the plan of treatment is first to give the finer anatomy and the physiology of the organ or system in question, and then the essential features of microscopic sections prepared from it are fully described. Each chapter is followed by a brief appendix in which the technic of preparation of the sections just described is given. The description is accompanied by carefully drawn plates in the same colors as the microscopic sections present. For example, turning to the chapter on the lymphatic system, there is first given a brief description of the lymph and the lymphatic system. Under the subdivision "Origin of the Lymphatics," the "lymph spaces," "lymph capillaries," "central lacteal of a villus," "perivascular lymphatics," "serous cavities," and "synovial sheaths and ursæ" are considered. Under other subdivisions of this chapter are "The Lymph Vessels," "The Solitary Follicles," and "The Lymphatic Glands." The sections described in detail are, (*a*) the "central tendon of the diaphragm of guinea pig stained with nitrate of silver," and (*b*) "section of lymph gland of mammal stained with hematoxylin or picrocarmine." Eight drawings in colors appear in connection with this chapter, four of them to illustrate the sections mentioned; one the perivascular lymphatics, while three are diagrammatic representations of a "serous cavity," a "solitary follicle," and "the origin, cause, and termination of the lymph channels."

This sketch of a single chapter will show the plan of the book. The arrangement of subject matter in such a methodical manner, and the excellence of the numerous plates (174 in all), are the features of the histology which will most commend it as a text-book and book of reference.

TRANSACTIONS OF THE AMERICAN SURGICAL ASSOCIATION. Vol. XIII. Philadelphia. 1895.

The thirteenth volume of the Transactions of the American Surgical Association, uniform in style with those which have preceded it, is a book of 516 pages. It contains a number of interesting articles, *e.g.*, five upon the "Operative Treatment of Cancer in Various Localities," by Homans, Conner, Wight, McGuire, and Gerster, and four others upon "Restoration of Joint Function after Fracture," by Carmalt, Sayre, Roberts, and Bradford.

It speaks well for some one's power of restraint that among the thirty-three papers there is none upon appendicitis, nor intestinal resection: neither is tuberculosis mentioned.

BOOKS RECEIVED.

Weekly Abstracts of Sanitary Reports, vol. x, 1895. The bound volume of these reports issued from the Surgeon-General's office makes a convenient and valuable book of reference.

Transactions of the Pan-American Medical Congress, held in Washington, D. C., U. S. A., September, 1893. The report is presented in two octavo volumes and occupies 2250 pages. The detail of the various sections as well as that of the general sessions seems complete and full, and makes an interesting and instructive addition to the literature of medicine and surgery. The newest and best thought from every quarter of the American Continent was contributed, and at once gave this congress a high rank among the scientific gatherings which have distinguished the latter part of the nineteenth century. To have distributed free of cost to the medical profession these volumes is an act of liberality on the part of the U. S. Congress, not soon to fade from the grateful minds of the many who have received them.

Transactions of the Michigan State Medical Society, 1896, makes an attractive volume of more than eight hundred pages, and contains many articles of more than passing interest.

Transactions of the Southern Surgical and Gynecological Association, 1895. A handsome volume of three hundred neatly printed pages. The good work so uniformly done by this association leads one to expect fine material in this, the eighth volume, and no sense of disappointment will attend its perusal.

Transactions of the American Orthopedic Association, vol. viii, 1895. This volume contains a large number of handsomely illustrated articles and their discussions, which must appeal to all exponents of this special branch of surgery.

THE MEDICAL NEWS.
A WEEKLY JOURNAL OF MEDICAL SCIENCE.

VOL. LXX. NEW YORK, SATURDAY, JANUARY 9, 1897. NO. 2.

ORIGINAL ARTICLES.

NEW METHOD OF PERFORMING INTESTINAL ANASTOMOSIS WITH SPECIAL REFERENCE TO ITS ADAPTABILITY TO INGUINAL COLOSTOMY AND SUBSEQUENT RESTORATION OF THE FECAL CURRENT.

BY J. A. BODINE, M.D.,
OF NEW YORK;
ADJUNCT-PROFESSOR OF SURGERY IN THE NEW YORK POLYCLINIC MEDICAL SCHOOL AND HOSPITAL.

THAT so many ingenious methods of performing intestinal anastomosis have an active and practical existence is proof that none of them is entirely satisfactory. Without mechanical contrivances it is a most difficult operation, and calls for exhibition of the highest surgical skill; with mechanical aids it is less difficult, but these have not yet proved entirely reliable or harmless. The mortality as it stands today is high, partly because of dangers inherent in the operation, and partly because of delay entailed by a course of temporizing therapeutics, thus impairing the patient's strength. The great activity of surgical thought in this particular field will no doubt sooner or later solve the question of a rapid and safe method of approximating the two ends of the severed intestine; and it is with the hope of contributing to this achievement that I offer the results of my individual efforts.

The method to be detailed is the outcome of thought directed toward improving the spur in inguinal colostomy. It can readily be seen that if the spur stands flush with the skin surface, no fecal matter can enter the portion of colon beyond the site of operation, but the spur formed by suspending the gut over a supporting pin or rod has no thickness or rigidity, and the constant dragging weight of the intestines within the cavity soon pulls its upper border below the level of the skin surface, thus permitting passage of fecal matter into the lower portion of the intestine (Fig. 1). It occurred to me that the mesentery of the loop might be folded so as to stiffen the spur by stitching together both sides of the two limbs of the flexure. This, being tried on a dog, was found to furnish the desired remedy, and, furthermore, was capable of easy and rapid execution. As this acute flexion of the gut upon itself forms a septum fully an inch in width between the two rows of sutures, it will be readily seen that simple division along the center of this spur removes all obstacle to the flow of the current beyond the abdominal opening into the lower portion of intestine. We therefore have a simple means of restoring continuity when the proper time arrives.

Five dogs have been subjected to the operation in its two different applications, *viz.*: (1) Enterostomy, as recommended for intestinal anastomosis and temporary anus, by *excluding* the mesentery from between the two rows of sutures, and (2) colostomy, as recommended for permanent anus, by folding the mesentery between the two limbs of the flexure. The details of two of these experimental operations are given here, the others being reserved for a subsequent paper. A large male dog was chloroformed by the author, November 13, 1896, and the usual incision for colostomy made. The parietal peritoneum was stitched to the skin, the colon identified and drawn through the incision. On account of the short mesentery, but six inches could be exposed. The two limbs of this loop were laid side by side, acutely flexing the center, and sutured together for a distance of three inches. The first line of sutures was placed parallel with and close to the mesenteric border, the second row along the line of the convex borders. This was done by a continuous suture, requiring but one long strand of silk. The loop was now returned to the cavity until the point where the suturing commenced was on a level with the skin, and stretched into the abdominal wound. The protruding cap of the knuckle was clipped off close to the surface. Three days later the dog was again anesthetized, and the artificial anal orifice washed with a stream of warm bichlorid solution. The septum between the two intestinal orifices could be clearly seen, and by passing the blade of a pair of blunt-pointed scissors into each opening, was divided for a distance of 2½ inches. The bleeding was very insignificant, and *required no hemostasis*. The abdominal wound was closed by Byrd's method. For a number of days some fecal

FIG. 1.

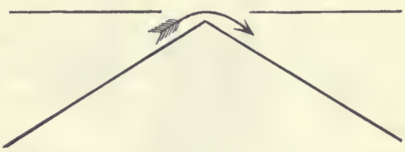

Diagram showing the intestinal spur drawn below the level of the skin surface by intra-abdominal tension, and fecal matter passing into lower portion of intestine.

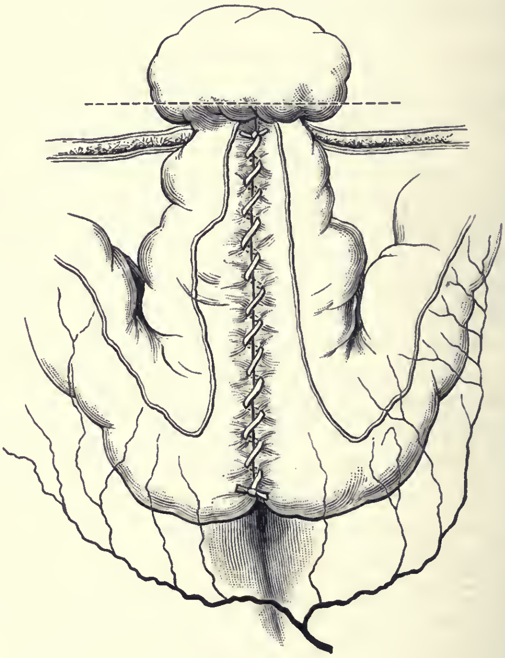
matter oozed through the wound, but it eventually closed, and the dog is perfectly well. This dog is being preserved, to show at a coming medical society event.

Wishing to test the method in the hands of another operator, Dr. J. Shelton Horsley of this city kindly chloroformed a small male dog on December 15, 1896, and performed the operation as recommended for permanent colostomy. The sigmoid flexure was drawn through the incision and a loop sutured together for a distance of three inches. The mesentery, in this case, was *folded in* between the two limbs by running the line of sutures on each side midway between the convex and mesenteric borders. After passing back the sutured loop and stitching it into the abdominal wound, the protruding cap was clipped off. One week later the dog was killed and the specimen removed. The gut presented two circular orifices at the abdominal opening, with the septum between clearly defined and standing flush with the skin surface. The lines of sutures were buried beneath a layer of organized lymph and the two opposed walls composing the spur were firmly welded together by this same material. This spur was extremely firm and rigid, measuring fully one-third of an inch in thickness. Looking at the specimen from the outer end, it resembled the muzzle of a double-barrelled shotgun, *the width of the septum measuring exactly the same as the diameter of the dog's colon.*

Suturing the parietal peritoneum is a procedure of great value. The cellular planes between the muscular layers are shut off from infection by the feces, preventing cellulitis, abscess, etc. The mesentery in dogs being short, but six inches of gut could be exposed, which gives a loop of only three inches when doubled upon itself. In man, eight or ten inches should be brought through the incision when possible. This gives a spur four or five inches long, which can be divided for three or four inches to furnish an ample anastomotic opening.

Without going fully into the defects of the present methods of intestinal anastomosis, I beg to point out that end-to-end suturing is time-consuming, and, even in the most skilful hands, leakage of intestinal contents between the sutures is frequent, as proved by the high death-rate from septic peritonitis. Lateral anastomosis by hand-suture is open to the same criticism. The mechanical aids, such as the vegetable, bone, and rawhide plates of Dawbarn, Senn, and Robinson, respectively, and Murphy's button, are open to many objections, and are considered unsurgical by some operators. The method I offer is applicable to any portion of the intestine which possesses a mesentery. I have not had the opportunity to practise this method in its entirety on man, but in dogs it works perfectly. Theoretically, it bears the stamp of the three ideal requisites, namely, (*a*) rapidity of execution, (*b*) safety of approximation, (*c*) ample anastomotic opening. Rapidity of execution is a desideratum of great value. Exposure of the abdominal contents, especially in the weak and non-resistent, has frequently brought about a fatal issue when the union between the intestinal ends has been perfect. Every one to-day recognizes the value of rapidity in intestinal work, and knows that each additional minute of exposure contributes to shock. Safety—by which I mean accuracy—of approximation, is the essential feature of the operation. The faulty application of a suture, bringing about leakage of intestinal contents, produces a certain fatal result. The third requisite, of ample anastomotic opening, has been one of the weightiest objections to the very ingenious Murphy button.

Fig. 2.



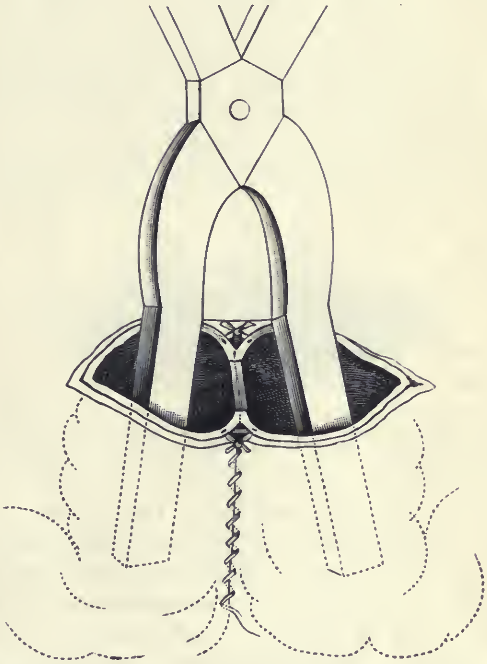
Intestinal anastomosis. Showing one side of the loop after it has been sutured, passed back into the cavity and stitched into the abdominal wound. The lesion is left protruding, and the dotted line indicates where protrusion is to be clipped off.

The method which I propose is as follows: After the usual preparation of the patient for laparotomy, and free purgation when possible, an incision of sufficient length is made down to the peritoneum. All hemorrhage being carefully arrested, the peritoneum is incised and a sterile pad introduced to protect the intestines while the parietal peritoneum is stitched to the skin with a continuous catgut suture. The lesion which has necessitated the operation (tumor, stricture, etc.) is now sought for and, when found, is drawn through the incision until six inches of healthy gut on each side of the piece to be exsected is exposed. The two limbs of the loop, with the lesion as apex to the knuckle, are laid side by side, the convex borders in apposition, and a running stitch of fine silk, beginning at the points where exsection is desired, is carefully inserted, uniting the two pieces of intestine close to and parallel with the mesenteric border for a distance of six inches (Fig. 2). The sutured loop is then passed back into the abdomen until the point where the running suture begins (*i.e.*, the point where the intestine is to be exsected), is on a level with the skin surface, and the loop stitched into the abdominal wound with a continuous suture of catgut. This leaves the lesion protruding. If waiting is permissible, twelves hours should elapse, and then under cocain anesthesia, the protruding intestine is snipped off with scissors level with the skin. Having established an artificial anus, we may now wait any length of time in order that the lymph thrown out may solidly unite the apposed walls of the sutured portions.

The next step is the reëstablishment of the continuity of the intestine. With a finger inserted into the opening of each portion of intestine, to define the spur and guide the cutting instrument, the septum is divided with scissors along its median line for a distance of four inches, or, better still, a clamp such as H. H. Grant's of Louisville, which crushes rather than cuts, may be used (Fig. 3). A moment's study of the accompanying illustrations will make the technic perfectly clear. It will not be necessary to take out a wedge-shaped section, as the passing of the feces will prevent reunion of the septum. The abdominal wound may now be closed by any method which suits the surgeon. I prefer the method of Szymanowski[1] or Byrd. The technic of the latter is here appended. In the most expert surgical hands, the integrity of the line of sutures approximating the two ends of severed intestine in an anastomosis is a matter of uncertainty, and the subject of grave anxiety to the surgeon until a movement of the patient's bowels demonstrates successful union. By the author's method, this danger of leakage at the line of co-aptation is entirely removed. Exsection of the lesion is performed *outside* the abdominal cavity and the anastomosis effected subsequently with little or no additional risk. In the hands of experienced operators, the mortality of stitching the loop of gut into an abdominal wound and, after plastic exudation has sealed this line of stitches, clipping away the protruded portion, under cocain anesthesia, would probably not exceed two in a hundred. Add to this, for completion of my operation, a simple division of the spur, which should be devoid of danger, or nearly so, and it would seem that the method offers great hope of being a life-saving procedure.

In inguinal colostomy the operation is to be considered a failure if any fecal matter passes the opening into the distal portion of intestine. The originators of the different methods now in use admit that in this respect the spur is incompetent. Mathews of Louisville, Ky., who uses two hair-lip pins thrust through the mesentery, says: "The fecal current is not always diverted." Kelsey of New York, speaking of colostomy in general, takes the inefficiency ot the spur for granted, saying: "Relief of pain and tenesmus is sometimes only partial, because a portion of the feces passes the opening." The use of any mechanical support, such as glass rods, pins, etc., to hold the loop of gut in the abdominal wound while adhesions are forming, is, like the mechanical contrivances for anastomosis, incompetent and unsurgical. The spur will sag below the level of the skin when the support is removed. Of the present advocated operations, the nearest approach to efficiency is Allingham's "mesenteric stitch," but Mathews, who is a great admirer of this method, admits that it occasionally fails to completely divert the current. According to Allingham, procidentia occurs in six-

Fig. 3.



Intestinal anastomosis. Showing the septum to be divided in restoring the fecal current. Grant's clamp in position for the division. (In permanent colostomy this septum remains as a rigid and effective spur. Contrast this with diagram 1, which shows the spur formed by suspending the gut over a supporting pin or rod.)

---

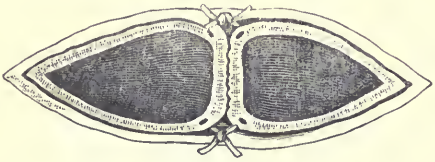
[1] "Wyeth's Surgery," second edition, page 702.

teen out of sixty cases, and to avoid this he has advised drawing the gut out of the wound until the mesentery is taut, stitching it, and, subsequently, under ether narcosis, excising all the protruded portion with a specially devised clamp. He confesses that cutting away such a large mass of intestine adds to the gravity of the operation, and Treves criticises the procedure as unnecessary and severe.

Cripps draws the intestine out of the wound, passes it over his finger back into the abdomen until the mesentery is taut, and then stitches it. This plan is preferable to Allingham's, but it may be objected that the opening is placed too high up the gut. The nearer the opening is to the rectum, the more comfortable will be the patient. The fecal mass being more or less solid, the movements can be confined to one or two a day, with the aid of diet and astringent medicines; while, if the opening is high up the gut, there is the annoyance of a continuous excoriating and offensive fluid discharge.

The last and most formidable criticism of the present technic in inguinal colostomy, is the difficulty of reëstablishing the fecal current, should this be desired. A laparotomy and intestinal anastomosis must be done with all the attendant dangers of handling the septic anal orifice in the peritoneal cavity. Depuytren's clamp is hardly to be considered. "Nearly all attempts to reëstablish the anus at its natural site after colostomy have signally failed." (Mathews). That such dangers attend the restoration of the intestinal continuity has probably done much to place the operation in the position of being applicable only to ineradicably obstructive lesions of the colon. No one would dare, in the face of the high mortality, to advocate or perform colostomy for acute lesions, such as inflammation, ulceration, etc., which physiological rest might cure. The operation which I propose will obviate these three principal faults, *viz.*, (1) Inefficient spur, (2) procidentia, and (3) mortality from restoring the continuity.

Fig. 4.



Showing application of the first two sutures to be applied when stitching the loop into the abdominal wound. They hold the upper margin of the spur level with the skin surface.

In performing colostomy an incision is made one and a-half inches long, two inches inside of the spine of the ilium, crossing at a right angle a line drawn from the anterior superior spine to the umbilicus. A sterile pad is introduced to protect the intestines, and the parietal peritoneum is stitched to the skin. When the colon is identified, it is drawn through the abdominal wound until a loop *twelve inches* long is exposed. If the anus is to be permanent, the loop is acutely flexed upon itself and a running suture of silk is placed along the line midway between the mesenteric and convex border on both sides, beginning at the apex of the knuckle and extending for *six inches* down the two limbs of the flexure, thus approximating the two serous surfaces and *folding the mesentery in between the limbs to stiffen the spur.* The sutured loop is then dropped back until the point, as shown in Fig. 2, is level with the skin surface. A stitch is passed through the skin into this point back through the skin and tied (Fig. 4). This must be carefully and accurately inserted. The suture is repeated on the opposite side. The gut is now stitched in the abdominal wound with a running suture of catgut. Catgut as a material for suture in this operation is to be preferred to silk, as the latter is hard to find among the granulations when the time comes for removal, and, by capillarity, it infects the stitch-holes, giving rise to pain and sometimes abscess.

After an interval of forty-eight hours, if waiting is permissible, the protrusion is snipped off with a pair of scissors nearly level with the skin, cocain anesthesia being required. We now have a spur so stiff and rigid that it cannot be dragged below the skin level, and no feces, either solid or liquid, can pass into the lower portion. In a few days the plastic exudate around this fortified spur has so thickened that procidentia is prevented.

If the artificial anus is to be temporary and subsequent closure of the colostomy wound is desired, the line of sutures approximating the two limbs should be inserted *like those given for anastomosis*, which does not fold in the mesentery, and when ready for restoration, the spur is simply divided along its median line for four inches, as directed for anastomoses (Fig. 3). When the abdominal wound is closed we have a perfect and ample anastomosis between the proximal and distal portions of the colon.

Byrd's method for closing the abdominal wound is as follows:[2]

> "The skin on each side of the opening is caught up in a fold, in such a manner that the top of the folds meet easily over the opening of the bowel; an incision along the top of these folds, which is about three-quarters of an inch from the opening in the bowel, is then made through the skin and superficial fascia, and extended so as to form an ellipse enclosing the opening. That portion of the skin next the opening is then dissected up from the outer side, leaving it attached at the inner side to the opening in the bowel; it is then inverted and turned into the bowel. This procedure brings the raw surfaces in apposition, and throws the skin into the bowel, so as to form a

---

[2] "Kelsey's Diseases of the Rectum and Anus."

continuation of the mucous membrane. The skin on either side of this elliptical raw surface is now brought together by passing two stay sutures, with a shot and shield, back about an inch from the cut edges, and making traction. This brings the edges together and makes them rise from the abdomen like an inverted V. Where the skin meets at the apex of the V it is fastened with a catgut suture. The portion of the skin in the intestine is shaped like a V, and that outside has its apex immediately above the apex of the lower one. By this procedure fully an inch and a half of raw surface is brought in contact over the opening in the bowel, thus almost insuring sufficient adhesion, while the V raw surfaces of the skin that is inverted into the bowel act as a valve, and are held in apposition by the pressure of the contents of the bowel."

I have used this method of making the spur in one case, but, as yet, have not had the opportunity of attempting restoration of the gut.

L. M., Chicago, a jeweller, sent to me by Professor A. R. Robinson, was suffering from a recurrent tumor of the rectum which had been diagnosed as sarcoma. He had been operated on three times, with prompt recurrence each time. When I saw him the anal sphincters and rectum, for a distance of three or four inches, had been removed. The growth had recurred and involved the tissues around the outlet, as far up as the end of the severed gut. Believing it to be sarcoma, and further attempt at local removal unadvisable, inguinal colostomy was proposed and consented to. On July 15, 1896, at the New York Polyclinic Medical School and Hospital, I did the inguinal colostomy and constructed the spur in the manner just detailed. Up to this date no procidentia has occurred, and absolutely no fecal matter has passed beyond the opening. Dr. Robinson has since removed the growth by medicinal means, in spite of the fact that the diagnosis was that of sarcoma. The patient, however, prefers to keep the artificial anus, as the anal sphincters have been removed.

The additional operation of closing the abdominal wound, advanced as an objection to the method, could scarcely be defended if mortality is lessened. In this regard it is highly probable that the free and ample anastomotic opening, secured by dividing the septum for four inches, would permit the artificial anus to close by granulation, and if division of the spur could be accomplished without general narcosis, a second operation would be unnecessary. Liability to ventral hernia is an objection anticipated, but it is a matter of minor import compared to the saving of life. It is probable that no perfection of the technic of colostomy will ever make it acceptable to either surgeon or patient as a permanent substitute for the natural outlet; but, if the dangers of closing it and restoring the continuity of the fecal current can be obviated, the operation will have a wide field of application in those acute lesions of the intestinal tract in which temporary physiological rest would prove curative.

STENOCARDIA (ANGINA PECTORIS).[1]

By H. NEWTON HEINEMAN, M.D.,
OF NEW YORK.

IT is unfortunate that a celebrated man like John Hunter, the anatomist, should have been among the earliest in whom the disease of angina pectoris was clearly recognized. The intense symptoms from which he suffered have ever since been considered as essential to a correct diagnosis, and our knowledge of this affection has thus been much retarded. Then, too, the difficulties in recognizing small, yet important, lesions macroscopically, and those besetting even histologic work have been additional factors in delaying a fuller appreciation of the conditions underlying it. Often, indeed, stenocardia appears to be a symptom, but it is certain that time will confirm the claim we make that it deserves a special place among the cardiac disorders. In some cases we meet with markedly advanced cardiac and valvular disease and atheroma of the vessels, entirely without the symptoms of cardiac pain and its accompaniments, whereas in other cases we may be unable to recognize any marked lesion, and yet decided symptoms are present. That a definite cause must exist for such marked symptoms needs no argument, the important issue being the determination of the essential cause.

History.—Chirac, more than 150 years ago, tied a coronary artery. Morgagni observed calcification of the coronary artery, and referred to Crellius and Thebesius as having done likewise. Rougnon and Heberden recognized the symptoms of the disease, the latter calling it stenocardia. Jenner and Parry associated the symptoms and the lesion, Jenner making the diagnosis of Hunter's malady in 1793. In more recent times, Marshall Hall, appreciating the relations between the coronary-artery circulation and sudden cessation of the heart's action, gave utterance to views which were followed up by Erichsen, who, in 1842, devoted himself to experimental research upon the problem.

The labors of v. Bezold, Breymann, Samuelson, Cohnheim, v. Schulthess Rechberg, and Bettelheim, of Panum, G. See, Bochefontaine, and Roussy McWilliam, and by no means least, of our own countryman, W. Townsend Porter, have made more clear the physiologic relation between the coronary circulation and the action of the heart muscle. The contribution made by me to the distribution of the coronary arteries may possibly throw a little additional light upon this subject.

First, a few words as to the anatomy of the cardiac circulation. Having established the fact that the coronary arteries frequently terminate in comparatively large trunks, and, secondly, that the capillaries come directly from large trunks, and that the capillaries, by reuniting in little congeries, form regular reservoirs from place to place between the muscle-fiber and fasciculus, and that the anastomosis takes place between the capillaries, we can appreciate the fact that interference with a larger artery means interference with an enormous extent of capillary surface.

---

[1] Delivered before the Section on General Medicine, New York Academy of Medicine, November 17, 1896.

Porter's experiments have proven that experimental interference with the coronary circulation gives rise to changes in intraventricular pressure, causes fibrillar muscular contractions, and even brings the cardiac muscle to a standstill. Still further, that the intraventricular pressure and the character of the contraction and relaxation in one ventricle may be speedily affected by ligation of a coronary artery supplying the other ventricle.

Etiology.—In seeking for the cause of the condition, it becomes quite evident that it must be looked for first in the heart-muscle, secondly in the coronary arteries, and thirdly in the nerve supply. Degeneration of the heart-muscle fiber, or of the muscular fasciculus, change in the cement substance, sclerosis and atheroma of varied degree of the coronary vessels, degenerative changes in the nerve-supply, functional disturbance of the heart-muscle from impaired nerve function, and reflex vasomotor disturbance of the heart have all in turn been found as factors in the causation of the symptoms.

But views have been as numerous as the authors who have written upon the subject, and naturally have varied according to the physiologic or pathologic experience of the writer. Osler quotes the old views of Allan Burns, readopted by Potain, that the anatomical condition is one of transient ischemia of the heart-muscle, because of disease and spasm of the coronary arteries. Thoma speaks of sclerosis or thickening of the coronary arteries always being present. Heberden looked upon it as heart-muscle cramp. Traube, and many following him, Tyson among the recent ones, considered it the result of an acute cardiac muscular dilatation causing great tension of the ventricular walls, associated with diseased coronary arteries. Wood and Fitz speak of the cardiac dilatation being a result in cases in which the disease has existed for years. Lauder Brunton, in a very recent article, accepts the brilliant simile and explanation of Sir Grainger Stewart, who speaks of two factors—the heart and the arteries. If the arteries are diseased, and so resist the entrance of blood, we have pain from pressure on the nerves in the more elastic arterial walls or from cardiac overdistension; if, however, the heart is too feeble to drive the blood into arteries that are sufficient, we have cardiac overdistension from its own muscular weakness. In brief, Stewart says: "Believing that both cardiac weakness and more or less change in the arteries coexist, cardiac pain is generally due to weakness of the heart in proportion to the resistance it has to overcome." The reflex effects of the nervous system have long been recognized. Charcot has long since demonstrated that in gastric crises the heart is affected. Franck proved that the nervous terminal twigs of the aorta, when irritated, affected the heart and respiration.

The effect of mental emotion in disturbing the heart and vessels has been forcibly illustrated in the cases of the kidnapped slaves of Livingstone, many of whom died broken-hearted. An example equally pregnant is the following:

X., forty-eight years of age, an industrious porter, with healthy heart, was examined by me daily before and after his day's work. After continuing this for five weeks, I found that, on a certain evening, the transverse diameter of the heart had increased more than 1¼ inches as compared with the measurement of the morning. This difference exceeded any I had ever noted as the result of work. Upon questioning the man, he told me he had done only a very moderate day's work, but that just prior to his coming to me he had had a wordy quarrel, which excited him somewhat.

The case of a literary man, who suffered from cardiac disease and occasional attacks of stenocardia, is of interest. He found that at times when he worked under mental pressure he would have slight precordial pain radiating into the left arm. Upon recommending him to work less unremittingly, he reported that if when the pain came on he ceased work, or worked with less intensity, it instantly abated.

Sexual intercourse is often an exciting cause, and we can appreciate our own responsibility when the question of coitus between husband and wife is to be decided by our opinion. Even the taking of an ordinary meal may excite an attack, and the digestion of a small quantity of milk may even be the exciting cause. It is a well-known fact that persons suffering from gouty kidney, and hence from increased arterial tension, often have attacks of stenocardia. It appears, therefore, that all causes which tend to increase intra-arterial tension, and which tend to relax the heart-muscle or cause the organ to act spasmodically, or to contract irregularly, and thus produce dilatation or weaken the force of the heart's action, or causes which call upon a weakened heart to overcome sudden and even ordinary exertion and, finally, causes interfering with the proper nerve-control of the heart and blood-vessels will produce the attacks. To this last group the so-called Nothnagel category of stenocardia vasomotoria belongs, and, at times, Jacob's angiospastic cardiac dilatation.

The various exciting causes of the symptoms of the disease demonstrate that the spinal cord, through its motor and sensory branches, the cerebrum, the pneumogastric, the cardiac and celiac plexuses, and, at times, the vasomotor system, are the avenues along which the effects are carried.

The ideas heretofore held that in cardiac failure of every kind the liver, spleen, and kidneys become the subjects of slow engorgement is still true, but it is not the entire truth. In the first place, we must accept the fact that the heart in health is liable to slight variations in size and shape. In disease, this change becomes more marked. But the liver and spleen are likewise subject to these changes. For several years Schott and numbers of his friends, myself among them, have maintained that in a number of cases in which the heart was seen to get smaller after exercises and baths, the liver likewise diminished in size. Recently Heitler[1] of Vienna has demonstrated, and so confirmed the fact which has so long been contended for by Schott, that there are not only coincident changes in the volume of the heart with the volume of the pulse, but also changes in the volume of the liver and spleen with those of the heart and pulse. Heitler found that when the pulse was small in volume and the heart was large, the liver and spleen were large; and with a larger pulse- and smaller heart-volume, the liver and spleen were smaller in volume.

Pathology.—We find thickening, atheroma even to calcification of the coronary arteries and their capillaries, similar degenerative changes in the arteries of the body and changes in the heart-muscle and the cement substance varying in degree and extent. In a few instances, changes have been found in the sympathetic cardiac plexus and pneumogastric branches. I am certain that these latter cases will in time be increased in number, and the etiology be cleared up in a considerable number of cases in which the muscular and arterial lesions are found to be so slight, and yet in which the symptoms were so pronounced during life. I will be pardoned, however, when I digress to say that after death the macroscopic examination of the heart should never be relied upon alone, but a thorough microscopic examination should be made as well; and it is essential for the success of the latter that the heart-muscle be as fresh as possible, and that more than usual care be taken for its proper preservation. Injection of the coronary arteries will add materially in facilitating the study of how far the lumen of the artery is encroached upon. As an ex-

[1] *Wiener med. Wochen.*, 1896, No. 13.

ample of such degenerative changes found in the arteries which could not be recognized macroscopically, I ask attention to Fig. 1. The patient had stenocardial attacks for years, and died at the *Hôpital St. Louis*, Paris, of chronic Bright's disease. The presence of aortic lesions is strongly dwelt upon by many authorities as being so often present that their share in the disease must be considered. Aortic lesions, however, are those of adult life, as a rule, and when mitral lesions are also present, they have usually been acquired in early life. While these lesions may have preceded the symptoms of stenocardia by many years, the reverse also holds true, for as the suffering patient grows older, valvular lesions may gradually make themselves manifest, and may be the result, rather than the cause, in some cases. During the life of a patient, if examination reveals cardiac valvular lesions, or thickened or sclerosed arteries, or myocarditis, or cardiac arrhythmia, by which we can infer disturbed functional activity, the pathology is cleared up. In some cases I have found that an ophthalmoscopic examination of the fundus, by revealing degenerative changes of the arteries, or hemorrhages, aided me materially in arriving at a diagnosis when the lesion was little manifest in the superficial vessels. But in all cases of doubt the physician should apply the sphygmograph[1] and sphygmomanometer,[2] and, if need be, also the arteriometer,[3] before deciding that the vessels and heart are functionally and organically sound. It is not without reason that I say that a single examination decides nothing; several examinations, repeated at the same hour of the day on successive days, at the same digestive period, under well-arranged normal conditions of the patient, and in the same position, preferably that of lying down (sometimes when the pressure is feeble the uncertainty of the results compels the use of the sitting posture) should be made.

Symptoms.—It is generally agreed that men are more prone to these attacks than women, though I think the proportion in favor of men has been somewhat exaggerated. The ages between forty and fifty are those in which most men are attacked. Before entering upon the consideration of the symptoms, I must state that it is my firm belief that by far the larger number of cases of pseudo and hysterical angina are cases of true angina. When heart-pain recurs in its characteristic manner, and with some of its usual symptoms, my experience has taught me that sooner or later the signs become sufficiently certain for me to include the case under true stenocardia, and this in a considerable number of cases in which, *at first*, the usual examination gave no indication of real lesion. For me a patient must have a clear history of hysteria preceding or accompanying the attack of heart-pain, and have been under observation for some time before I, from a negative standpoint, place the case in the pseudo-angina category.

Again, it has been customary to consider as genuine cases only those in which the symptoms of pain were marked and unmistakable. For me, the mildest symptoms characterize a considerable number, or the early stages of a number, in whom lesions may be recognized with difficulty, or not at all, for a time. Experience has, in a certain number, made the lesion clear, after several years of observation. Next, as to the ultra-severe cases, it has seemed necessary to some authorities (Nothnagel and others) to place in a separate category the cases in which the severe general vasomotor disturbances occur. Such cases have been denominated cases of angina vasomotoria. To me, these are only cases with unusually severe complications, or else severe forms of the disease. While allowing for exceptional cases of pseudo and hysterical stenocardia, I prefer to include all cases, mild or severe, with feebly or fully developed symptoms, and with or without vasomotor disturbances, provided examinations, properly made, give us changes in arterial tension, or other vascular or cardiac functional or organic changes, as true cases of stenocardia.

The first and most marked symptom we must consider is pain. However, this must be differentiated from intercostal, neuralgic, and rheumatic pains, and from pain resulting from various accidental causes. The pain is sometimes simple discomfort; again a sense of oppression or compression, varying in degree and severity; sometimes sharp and lancinating, sometimes like that of a sword pushed through the sternum and back; sometimes there is a feeling of unbearable weight, accompanied at times by a sensation of cold in the same region; sometimes there is a feeling of distension or bursting within the chest, or, again, a sensation of burning. This most pronounced symptom of stenocardia, however, is usually referable to the heart, but not always beginning or ending in the heart, and sometimes, by reason of greater intensity at other points, is not clearly appreciated as a heart pain.

In the mildest forms, the pain usually begins over the epigastrium, the lower end of the sternum, or the mid-mediastinal space, and from here it passes upward toward the neck and to the left arm, terminating at the left shoulder, elbow, or one, or several, or all of the fingers. At times it radiates into the right chest and right arm also, or, passing downward, radiates toward the abdomen. As the attacks grow in severity, the accompanying symptoms grow in intensity. The feeling of constriction or fulness of the throat becomes almost a choking one, and the sensation of compression of the chest and epigastrium becomes absolutely unbearable from a sense of superhuman weight to be overcome. The sharp pain appears like that of a sword-blade, with the hilt pushed against the chest, the handle even being twisted about to intensify the suffering. Anxiety and restlessness, a sense of fear even of some impending catastrophe and death, pallor of the face and coolness of the extremities, followed at times by irregular suffusion of the face, and sudden, profuse perspiration, and even loss of consciousness supervenes. The fingers of the left hand, sometimes the entire left upper extremity (less often those of the right hand or extremity) become numb and useless for a time. The attack may become modified, the pain being more bearable for a short time, and then may return in full force, continuing in this way for from one to several days in very rare instances. Usually the attacks last from a few seconds to a few minutes.

---

[1] Dudgeon's. [2] von Basch's. [3] Oliver's.

In persons subject to the attacks, pulmonary congestion, with expectoration of frothy, bloody mucus, lasting from a few hours to days, may occur.

Examination of the heart may reveal no irregularity, but even in such cases I have always felt that the heart seems to be acting against depressing influences; its action is not free as it should be. In characteristic cases, the heart beats irregularly, sometimes tumultuously, with alternate feeble and strong beats, very suggestive of the condition of fibrillar contraction of the cardiac muscle. At times it seems to beat feebly, being almost arrested in its action, then beating irregularly, and gradually returning to its previous condition. Less often there is simple tacchycardia, with feeble beats. The pulse, as already said, may indicate nothing; again, it may be small and thready, or may indicate increased arterial tension, or may be irregular and slower, or even faster. In cases in which the attack goes on to a fatal termination, syncope soon supervenes, the heart gets feebler, edema of the lungs, with cyanosis and coolness of the surface, follows, and, with the usual symptoms of this complication, life quickly ebbs away.

Beyond these usual phenomena, other more marked vasomotor disturbances may occur. Thus the symptoms described under the separate heading of "Angina Vasomotoria of Nothnagel" may be superadded to the ordinary symptoms. As a rule, the symptoms are associated with attacks produced by exposure to cold. We have general spasm of the peripheral vessels, pallor, cyanosis, and subnormal temperature, and a sense of stiffness and inability to use the extremities. At times faintness or unconsciousness follows. This condition, supposed to depend upon diffused spasmodic contraction of the peripheral arteries, is found, according to the author, in cases in which the pulse remains regular, and there are no signs of cardiac disease.

There is still another form of vasomotor disturbance which may or may not be associated at times with cases of stenocardia, and that is the form called by Jacob "angiospastic cardiac dilatation," in which any of the internal viscera, the liver, spleen, kidneys, or lungs in most cases, may be the seat of engorgement. The kidneys, if not the principal seat of the lesion, sympathize with the system, and the albumin and casts temporarily eliminated show their passing congestion if nothing worse. There may be signs of pneumonia or pleuritis, which disappear in a few days, and there may be some edema. The temperature is slightly elevated. The condition may last from a few hours to a few days. The heart is usually acutely dilated, even when dilated before. The pulse is, of course, small. This condition may assume all forms, from the mildest to one threatening the life of the patient. In very mild cases, engorgement of the liver or lungs, when slight, is overlooked, and frequently in severe cases the condition is mistaken for acute infection from old ulcerated valves or chronic endocarditis. The life history of these cases is exceedingly variable. Some few patients never have but a few attacks, and die in an attack of moderate severity. A small number after having been subject to a few attacks remain well, and years after upon the first return of an attack of greater severity succumb to the attack. In a fair number of cases, which number is now being increased, the attacks are induced to subside, and the patient enjoys years of freedom. In others the attacks may last for an indefinite number of years; in some, slowly increasing in severity, in others varying to and fro, the patient's life being dependent upon his general cardiac and constitutional condition.

The treatment of the patient may modify the career of the disease, and the occupation of the patient may be such as to intensify it. If the sufferer cannot avoid the mental or other exciting causes of the disease, the symptoms and number of the attacks will be dependent really upon the exciting cause, rather than upon the lesions and underlying causes. And it is this psychical element that is largely responsible for making cases appear so contradictory as concerns symptoms and lesions. Prodromal symptoms exist in quite a number of cases. Frequently a feeling of fulness or slight sensation of pressure or discomfort or sense of uneasiness is felt in the epigastrium, lower or midsternal regions, before the symptoms of stenocardia set in definitely. Many patients recall that these irregular and uncertain sensations existed for months or years, appearing at long intervals for a few seconds at a time, long before they became the subject of stenocardial attacks. It becomes an open question whether such prodromal symptoms may not really be part of the attack itself. But in many instances, by resting or resorting to medication, or by getting the body warmed if it has been chilled, or getting rid of the exciting cause, whatever it may be, the real symptoms are averted, or if too late to abort the attack, it is made more moderate.

Diagnosis.—The seat and character of the pain and remaining symptoms, especially if arterio-sclerosis, with or without cardiac valvular disease, exist, makes the diagnosis certain. If cardiac disease is not present and there is increased arterial tension, the diagnosis is not difficult. In gouty subjects, even if the heart is not apparently involved and the arteries are thickened or pressure increased; and even if there be no apparent change in the arteries, gout with characteristic symptoms is very suspicious of stenocardia.

In all forms of myocarditis, whether primary or even secondary to renal disease, the symptoms should be considered as strongly indicative. Hypertrophy with or without dilatation of the heart, and especially cardiac dilatation, makes the diagnosis fairly certain.

The occurrence of the symptoms in men over forty years of age, more especially with aortic disease and arterio-sclerosis, is a combination of conditions that makes such symptoms especially significant and unquestionable. In cases in which the symptoms are as yet few, and the finger and ear cannot detect changes in the arteries and heart, the diagnosis should be kept in abeyance until the sphygmomanometer, arteriometer, and sphygmograph have been brought into requisition. It is a question I have not yet decided as to how far the capillary pulse instrument will be useful, but it appears to me that in time with perfection of the apparatus, it should have great value.

The differential diagnosis from that rare form of stenocardia due to the use of tobacco must be based upon the history of the patient and the peculiar cardiac condition accompanying chronic tobacco-poisoning. In a case of cardiac valvular disease, the differential diagnosis would be difficult. If, however, such a patient smoked so much as to make himself liable to stenocardia, the probability is that the symptoms would be indicative of true stenocardia; however, he might coincidently suffer from tobacco-poisoning.

The differential diagnosis which Huchard makes between true and pseudo-stenocardia, is for the most part untenable, and I feel certain that in following tradition he has adhered to the arbitrary division so long made by other equally great authorities. To maintain that "spontaneity," being "often periodical or nocturnal," "pain less severe," "sensation of distension," "duration one or two hours," are essential features belonging to the pseudo types, is by no means in accordance with fact, for true stenocardia may be characterized by the same symptoms. The occurrence of attacks in a young woman of an hysterical temperament, free from cardiac disease, taken in connection with a lack of the usual succession of symptoms but with the existence of dyspnea, favors the diagnosis of pseudo or hysterical stenocardia.

Prognosis. — The prognosis depends upon the nature of the cardiac lesion and condition of the blood-vessels, and upon the severity of the attacks. Patients may go on having fairly severe attacks for years even with extreme lesions, while in other cases moderate attacks prove fatal. Balfour relates a singular case, but it was in the person of an old man who, having had an attack, was free for ten years and succumbed to the next. In seeking to fix the future of such cases it is wisest first to determine how far the patient's condition and attacks are amenable to treatment, for much depends upon the vascular and cardiac condition, and the ability to moderate the attacks. But even in desperate attacks with edema of the lungs, we must seek to keep up the heart's action until the edema has subsided, for the spasm may have passed off and the patient's only danger be from the effects of the edema.

The patient's environments and the extent of his means to purchase comforts and save himself from the injurious effects of work, temperature and surroundings are additional factors that tend to regulate the probable length of life. Considering the large number of persons so afflicted, the prognosis while earnest should never be made too grave.

Treatment.—The treatment should be regarded under three headings, (1) prophylaxis, (2) general treatment, and (3) of the attack itself.

Prophylaxis.—A great many attacks are excited by the influence of cold. The avoidance of cold water, and even of tepid water to any large surface of the body on account of the succeeding chill, must be advised. Such patients must wash their bodies one part at a time, and have that part well dried and covered before proceeding to the next. Even the keeping of the hands well gloved, maintaining warm feet, protecting the mouth and nose from the sweeping cold wind or air are precautions that will save the patient from many an attack. The regulation of the patient's life and habits come under this category. Avoidance of mental worry and emotion, of over-exertion, and even needless exertion at times, is imperative. The patient must walk with deliberation, and the combination of talking and walking may be too great a strain for the heart until it is improved by general treatment. Tobacco should be absolutely interdicted, and all spirituous liquors as well. In persons who have always taken wine, a small quantity of a light Moselle or claret, preferably Moselle, may be taken diluted at dinner or, exceptionally, if the patient feels weak and in need of it. Over-indulgence in food must be guarded against. If the patient has the prodromal symptoms of an attack, the seeking of shelter, of a warm room, of warmth to the surface, or resting or lying down, may ward off an attack.

General Treatment.—This must have two objects, first, the improvement of the heart and blood-vessels, and second, the relief of engorgement in the internal viscera and capillaries.

For the improvement of the heart and blood-vessels, the use of potassium or sodium iodid in from 3- to 5-grain doses kept up for months is an old remedial agent of a certain, though not always satisfactory, value. The treatment by saline baths and by the Schott method of exercises, has a most potent effect in improving the condition of the cardiac muscle and vessels, and appears to have a direct effect in making the attacks less numerous and severe, and even in causing them to cease during a period of months or years.

The exercises with resistance or Schott movements should be carried out in the way indicated by me in a previous paper before the general meeting of this Academy. The movements are made in such a manner that the attendant can easily resist or hinder the movement, and the patient in seeking to complete the movement must overcome the resistance of the attendant. The movements must be made with especial care and caution in these cases, and the resistance at the outset must be at a minimum.

The artificial saline baths should contain from one to three per cent. of salt, and from one-fourth to one per cent. of chlorid of calcium, and should gradually be strengthened by the addition of carbonic acid. By a process now in the last stages of completion, it will be possible to prepare the saline effervescent and saline effervescent flowing baths by means of a simple apparatus, so that the carbonic acid will be intimately mixed with the water. Details of the manner of administering the baths and exercises for this and other cardiac conditions will appear later.

For the relief of visceral and capillary engorgement we may resort to medicinal agents. Although the baths and exercises do this to a marked extent the administration of a half-grain of calomel (well triturated) thrice weekly at bedtime, succeeded the next morning by a dose of Carlsbad sprudel salts, adds materially to the effect.

After the visceral engorgement has been much relieved, we can now use our nitrites, and, in some cases, nitroglycerin; for until visceral congestion is relieved it is only playing hide and seek to try and relieve the capillaries which are immediately clogged again by the nearest congested viscus. Having accomplished this, we will now find the cardiac tonics, spartein, strophanthus, strychnin, valerian, and, in suitable cases, digitalis, of the greatest utility.

The general tendency to anemia and defective oxygenation must never be lost sight of, and general tonics, including the use of oxygen gas, as recommended by A. H. Smith, will be of excellent service.

The Attack.—The treatment of the attack, includes the use of nitrite of amyl in from 3- to 5-drop doses, poured upon a handkerchief, or taken from a glass pearl in similar manner, and inhaled.

The use of nitroglycerin in 1–100 grain doses is of less rapid efficacy. It may be repeated once in three or four hours, or at even longer intervals. In a severe attack it may be given at half-hour intervals, but should be given guardedly. In some patients the effect of nitroglycerin is immediate, in others very slow. Hypodermatic injections of morphin, with or without atropin, is often of great service.

The use of ether or chloroform, with or without valerian internally, relieves moderate spasm, and is somewhat stimulating. Local counter-irritation—by issue, sinapism or blister over the precordium, or the actual cautery over the precordium, or applied over the hepatic region in some cases, and the application of electricity, may be resorted to. Sometimes the local application of the hot water bag is of service. Exercises given with extreme caution has in my own hands sometimes given some relief to the acute symptoms.

To recapitulate, I wish to emphasize that the treatment should not be haphazard, but *systematic*, if we would accomplish anything; and considering the suffering entailed by this disease and the danger involved, such attention upon our part is essential and called for.

First we must remove *exciting* causes of every kind, and next relieve the visceral engorgement that has long existed because the heart was too weak and the vessels not elastic enough to keep up proper venous circulation, and, having gotten rid of the vis-a-tergo, we relieve the capillaries by appropriate remedies and coincidently stimulate the heart, which can now act better because its capillary embargo has been raised. The success of the treatment depends upon the following out of the sequence just suggested. The comfort to be guaranteed to the patient, and the prolongation of life, are sufficient rewards for patient toil and scientific interest. I add a few cases taken at random from a large number, illustrative of the manner and results of treatment.

Case I.—A. S., aged fifty years, a Russian, came to Nauheim in the summer of 1895. Family history negative. Had syphilis. In 1875 had severe rheumatism and marsh fever. Lived in Sardinia. In August, 1893, had his first attack of angina. Diagnosis of stenocardia by Professor Müller of Budapest, by whom he was put upon iodid. In October, 1893, iodid was stopped, and patient ordered a cold-water cure at Budapest. He grew worse, and the treatment was discontinued. He went to Professor Oser, in Vienna, who said he had gastric trouble. In November, 1894, was seen in Vienna by Abeles and Nothnagel. Nothnagel recognized his cardiac disorder, diagnosticating gallop-rhythmus with myocarditis. Next saw Professor Muri of Bologna, who renewed the iodid treatment. The prolonged iodid treatment and his illness had made him profoundly anemic. He now suffered from constant attacks of angina most of the day. The attacks came on after every meal and every movement. Even while asleep he would not be entirely free from them. The simplest food—even milk—caused an attack. Finally they became so intense that the patient often became hysterical and cried with agony. During this time he was in bed for months. He noticed that if he yawned severely he got relief. Pain usually began in the epigastrium, then went upward and across the chest into the left arm and hand and over the left shoulder slightly; it rarely went into the right side, and if so, was not so severe. In February, 1895, he consulted Dr. Secchi and others in San Remo, For two months previously he had been again in bed and taking iodid. Secchi now stopped the iodid and ordered strophanthus during April and May, 1895. Nothnagel came to San Remo in May, 1895, and advised him to go to Bad-Nauheim as a last resort, and in July he came there.

From July 4th to 14th he was given nine saline baths at a temperature of 32° to 31° C.; duration eight to eighteen minutes. From July 16th to 30th there were administered twelve effervescent saline baths at a temperature of 31° C.; duration eight to twenty minutes. August 1st to 12th he took nine effervescent flowing baths at a temperature of 29° and 30° C.; duration twelve to twenty minutes. To the saline baths from one to two liters of *mutterlauge* had been added.

After the first week daily exercises with resistance were given. He made a complete recovery to the extent that all the angina attacks disappeared.

In August, 1896, he returned to Nauheim and reported to Dr. Schott that he had remained free from attacks, barring a slight suggestion of an attack in the shape of mild prodromal symptoms. He had taken no treatment of any kind meanwhile.

He repeated his treatment in the summer of 1896, and in the fall reported himself, in a letter to me, as being free from every symptom.

Case II.—X., aged forty-three, American, came to Nauheim in the summer of 1896. Family history: Father died of cerebral apoplexy. Mother has cardiac disease. Sister died of chronic Bright's disease.

Patient never had had rheumatism or syphilis, and was well up to three years ago when he began to complain of dyspnea on exertion, had precordial discomfort, and was anemic.

Six months ago began to complain of attacks of angina, which came on by day and by night. Attacks occurred at times without apparent cause, and always under the influence of cold. Diagnosis of aortic stenosis had been made in 1893. After two weeks of saline baths with *mutterlauge* (1 to 3 liters), temperature varying from 33° to 31½° C., the attacks ceased, and up to November, 1896, had not returned.

Case III.—X., aged sixty-one years, native of Batavia, came to Nauheim in 1895. No history of rheumatism or syphilis. Excessive smoker. For years patient had worked under pressure in a hot climate. He maintained good health until he suffered severe shocks from family bereavement. He then began to complain of vertigo and headache, and of malaise, weakness, loss of appetite, and marked dyspeptic symptoms. He suffered from attacks of cardiac arrhythmia, which were followed by a sensation of faintness and slight syncope. He had more or less sharp and lancinating pain in the precordium, going into left shoulder and passing down to left elbow. This pain was brought on by any exertion or slight excitement. The noises of his beating heart awoke him at night. Examination revealed aortic disease (stenosis and insufficiency), and although he discontinued smoking upon his doctor's advice, he did not improve. He left Java and came to Holland in the winter, and rested in Holland for four months, where he was treated without result. After this treatment, in the summer of 1895, he came to Nauheim suffering as before. Examination revealed an intermittent arrhythmical heart, myocarditis, and general atheroma, aortic stenosis and insufficiency. Patient complained of angina, dyspnea, and symptoms as above, and was unable to walk without distress.

After six weeks' treatment by baths alone his symptoms disappeared. It was noted that whereas before the individual bath his pulse was 80 to 82, afterward it was 66 to 68. He remarked to me: "I am wonderfully better." He was able to go about without pain, and his heart had become reduced from 15 cm. to 12½ cm. in its greatest transverse diameter. The improvement was maintained throughout the winter of 1895–1896, and in the summer of 1896 he returned to Nauheim and repeated the treatment. He left in most excellent spirits and with no symptom of discomfort.

Case IV.—Miss X., aged thirty-six, school teacher, German. Mother subject to chronic gout. At seven years of age patient had had pleurisy and periostitis of left chest. Fairly well till her sixteenth year; became anemic, and for two years had epileptic attacks. Then suffered from chronic bronchitis for two years, with a slight return of epilepsy. Was profoundly anemic all this time, and suffered from chronic malarial poisoning. Menses appeared (but scanty) at nineteen years of age. From her twentieth to twenty-eighth year she was anemic and continued to have constant headaches, pains in joints, and swelling of legs. When thirty-one years of age she suffered a sudden shock, from which time her heart's action became intermittent and she had a frequent sense of intense precordial pain. She was examined in 1891, and a distinct mitral regurgitant, together with a double basic murmur, was recognized.

She reported that in the spring of the year her cardiac symptoms were always most severe. The heart action was always most intermittent at that time, so as to make her feel faint very often during the day. She could not sleep, and the precordial pain was accompanied by the sense of impending danger and death. She tried rest and mountain air for three summers, with only temporary improvement.

She came to Nauheim in 1894.

From July 7th to 29th she took fifteen thermal saline baths, temperature varying from 32½° to 32° C.; duration, ten to twenty minutes.

From July 30th to August 6th she took six thermal effervescent saline baths; temperature, 31° C.; duration, eight to twelve minutes.

Although she left Bad-Nauheim, having gained eighteen pounds in weight, yet the conscious improvement began only a fortnight after she reached her home. She remained well the entire year, passed the spring without any symptoms, and when I examined her in July, 1895, she had a feeble mitral regurgitant murmur, but a perfectly regular heart.

She repeated her treatment the next year, 1896, and reported herself able to go about her duties all the year without hindrance.

IRITIS AND ITS TREATMENT.[1]

By LOUIS F. LOVE, M.D.,
OF PHILADELPHIA, PA.;
OPHTHALMIC SURGEON TO ST. MARY'S HOSPITAL, TO THE HOUSE OF THE GOOD SHEPHERD, ETC., PHILADELPHIA.

It is not my purpose this evening to go into the different forms, nor to enter into a study of the etiology of the various kinds of iritis, but I desire to call the attention of the Society to a case of simple plastic iritis recently treated at the eye clinic of St. Mary's Hospital, not on account of its rarity, but because its history is typical of a number of cases of neglected disease which are seen at every hospital.

G. D., aged thirty-two, came to the clinic, March 17, 1896, with the following history: Always had good vision until one week previously, when he awoke one morning with considerable pain in the right eye and intolerance of light; nevertheless, he managed to work that day and the next, his eye being protected by a shield. On the evening of the second day, the pain being then very great and the eye greatly congested, he applied to an apothecary who gave him some drops, presumably sulphate of zinc solution. It is needless to say that the drops aggravated all the symptoms, and after two visits to the apothecary, he came to the eye clinic at St. Mary's Hospital.

On examination a typical case of iritis was found, the iris firmly adherent to the anterior capsule of the lens, the anterior chamber filled with flaky lymph, and the media so obscured that it was difficult to see the fundus. No deeper inflammation had, however, as yet set in.

As I have said, this history is not at all unique, and I am sorry to add that it is not always apothecaries who commit these blunders. Yet of all the inflammations to which the human body is liable, iritis should be the one most readily recognized. The whole progress of the disease is exposed to view and the symptoms are characteristic and well marked. Certain cases of iritis might be mistaken for more serious eye troubles, such as glaucoma, but there is no excuse for the mistake of supposing it to be simply a conjunctivitis or "cold in the eye," as was apparently done by the worthy apothecary in the case which I have related.

The pain in iritis is very characteristic. It commences with a heavy deep pain as if the eyeball was being pressed upon by the fingers and this pain grows more and more severe as the inflammation progresses and is accompanied by shooting pains which usually radiate along the branches of the fifth nerve. Supra-orbital neuralgia is thus a prominent symptom, but it is accompanied by the deep pain in the eyeball itself. Gradually the pain becomes more and more neuralgic, intense paroxysms coming and going and increasing toward night. Frequently these are accompanied by flashes of light. All these symptoms are of intra-ocular pressure, and an active inflammatory process. The pain is totally different from that of any inflammation, however severe, external to the eyeball.

Not less characteristic are the objective symptoms. Before any lymph is thrown out which is apparent to the eye, the iris is discolored and contracted and begins to lose its power of movement; the pupil loses its shiny blackness, there is deep ciliary injection, and a dull appearance of the cornea. The immobility of the pupil is almost pathognomonic. If we exclude certain nerve troubles which in no other way resemble iritis, immobility of the iris and contraction of the pupil necessarily indicate some morbid process going on in the iris itself. When the disease has progressed to the formation of lymph and apparently the entire fixation of the iris, there can be absolutely no doubt of the nature of the disease, but even in the very early stages there is little excuse for a mistaken diagnosis.

I have referred only to the most characteristic symptoms. Photophobia which is marked is common to all inflammations of the deeper tissues of the eye. So, too, is injection of the conjunctiva, though to the educated eye there is marked difference in the congestion which accompanies iritis from that resulting from any other cause. It is so with the other symptoms set down in books. There is one condition, however, which may occasionally puzzle the physician who has had little experience in eye troubles. I have seen cases of glaucoma in elderly people which were complicated by an inter-current attack of iritis, and in these cases the symptoms of iritis are to a certain extent masked by the presence of glaucoma; and again, in inflammatory glaucoma there is frequently an exudate from the pupillary edge of the iris. While the acuity of vision is lost in both diseases, the decrease is much less in iritis than in glaucoma, and to the educated touch, as a rule, the tension of the ball furnishes a ready guide to diagnosis. The fact that iritis may occur during the progress of glaucoma should make us cautious in the treatment of the former disease in elderly people, where there may be a history of approaching glaucoma. In serous iritis we should also be on our guard, lest in curing the iritis we increase the blocking up of the canals of the ciliary body and thus increase the glaucomatous condition.

---

[1] Read before the Phila. Northern Med. Soc., October 16, 1896.

In my opinion it is a matter of very little practical importance to determine whether an iritis is rheumatic, scrofulous, cachectic, or syphilitic in origin. As far as the treatment is concerned the same course is adopted in my practice, whether the patient confesses to syphilis or not. Of course, if iritis occurs during the progress of a rheumatic attack, or if there is a distinct history of rheumatism or gout, then remedies directed to these conditions should be employed, but taking the average case of iritis, with which we are all so familiar, the treatment should be conducted on the same general grounds, no matter what we have concluded the etiology to be.

The treatment of iritis has progressed but little since the early days of ophthalmology, and for the simple reason that if adopted early, the old fashioned treatment is eminently satisfactory. As in the days of our fathers, it consists essentially in the free exhibition of mercury, of local sedatives and derivatives, and in the free use of atropin. Mercury is best administered by inunction, the system thus rapidly coming under its influence. It should be remembered that the general condition of those attacked by iritis is usually poor, and that the stomach is not rarely irritable, and the digestion impaired. Internal medication should therefore be avoided as much as possible, except so far as is useful to build up the system and correct disorders of digestion. The use of mercury should be pushed to the point of tolerance. "Gently touch the gums," is the good old rule which is probably not very far wrong. Iodid of potassium is of little use in the earlier stages of the disease, but must be used after the inflammatory stages have passed, and when the mercury has been pushed almost to the point of salivation. If, unfortunately, your patient should object to inunctions, then some other form of mercury than the ointment must be used, the protiodid or bichlorid internally, or, better still, the subconjunctival injections as used by Abadie.

Local treatment to reduce the inflammation is very efficacious. I usually employ the Hurtelope or Swedish leech applied to the temples. Hot water fomentations applied to the eyeball are useful in allaying pain, and possibly in lessening the congestion, and should be freely used at frequent intervals and as hot as can be borne. A boric acid solution should also be employed.

But the chief treatment is the use of atropin, which should be administered both early and late, and in sufficient strength to thoroughly dilate the pupil, and at such frequent intervals as to maintain the dilatation. In the early stages the use of a solution of four grains to the ounce of the sulphate of atropin, applied every four hours, or even more frequently, is necessary to bring about this result. I have found good effects from combining cocain with the atropin in the earlier stages; it lessens the pain and aids in the more rapid dilatation of the pupil. After full dilatation has been obtained the cocain may be dropped, but the use of atropin, until all inflammation of the iris has disappeared, is absolutely imperative. In uncomplicated cases, which are seen at an early stage, the progress is very favorable. With neglected cases, complications are very liable to occur. The most simple is posterior synechia, which is altogether too frequently seen in eye-clinics, but it is unnecessary at this time to more than refer to the fact that most serious complications are more liable to follow neglect or maltreatment.

I have been greatly struck by the tolerance of mercury evident in many cases of iritis. I have seen numbers of cases which, as far as I could determine, were non-syphilitic, which bore readily the absorption of two to three drachms daily of mercurial ointment, for weeks, and even months, with no symptoms of ptyalization. In these cases, the mercury was continued until the eye whitened and the evidence of deep injection lessened. Mercury, in these cases, acted as a powerful tonic, the general health improving even more rapidly than the inflammation subsided, and it is in these cases that the most successful results are seen. I have already referred to the necessity, in many patients, of attending to the general health. As the majority of cases of iritis occur in patients whose systems have been run down by the presence of syphilitic or other poisons, the Turkish bath is especially useful, and tonic treatment should never be neglected.

In conclusion, I have only to impress upon you the facts that iritis is readily recognizable and is a most tractable disease if taken in time. The treatment is simple and effective, and there is no reason why nearly every case of iritis coming under competent care should not make a good recovery.

MENTAL COMPLICATIONS FOLLOWING SURGICAL OPERATIONS.[1]

BY J. T. WILSON, M.D.,
OF SHERMAN, TEXAS.

THE subject of mental disorders produced by or following surgical operations has not been discussed to any great extent, and until within the past few years only a passing notice has been given it. Dr. T. Gaillard Thomas reported six cases to the New York Academy of Medicine in April, 1889. He could find only twenty cases recorded previous to that date, and states that "prior to 1887 there was nothing in the way of literature on the subject." After Thomas called attention to this complication, quite a number of cases were reported, but I find in my investigations in this field very few complete histories accompanying these reports. This important part of the subject has been much neglected, and therefore a study of the literature is somewhat disappointing. The various mental disorders of traumatic origin, if I may use the expression, are not so rare as is supposed, and I presume every surgeon has met with cases during his career. They are sufficiently frequent to elicit careful consideration and special study in order that they may be prevented, or properly treated, when they have developed.

It is a strange fact that while surgical operations will sometimes cause serious mental disturbance, on the other hand, these same operations will sometimes cure them, and especially is this the case with some melancholiacs. Many females laboring under attacks of melancholia caused by some disease of the genital apparatus, have been cured when relieved of the physical defect by operation; others have been much improved, and yet others have received no benefit.

The question may very properly be asked, why a surgical operation should produce an attack of insanity. This can no more be answered satisfactorily in every case than can the question why some persons become insane from the many other causes to which it is attributed; for in most cases these mental complications are a surprise, and no good reason can be given why they should follow; in others, however, a logical explanation might be arrived at. If the patient is a high-strung, nervous individual, easily excited and unable to bear pain, the great and increasing dread of the anesthetic, or the thought of the operation, or both, will so affect him that he will lose control of the will-power, and the explosion will come after the operation and reaction from anesthesia. In many of these cases, probably a majority, there is an hereditary taint or a strong neurotic tendency. I think it has been the observation generally that females are more subject to these mental outbreaks than males, not because they cannot endure pain with equal fortitude, but because they are, as a rule, more nervous, more excitable, and more susceptible to the extremes of mental emotion. Nervous explosions, traceable to operations upon the female genitalia, are of comparatively common occurrence, because a greater number of operations are now performed in connection with these organs than upon other portions of the body; but this sequel is by no means confined to operations upon these parts. Polk has stated that he preferred not to operate upon patients who had previously shown an abnormal mental activity.

To anesthesia has been ascribed the cause of the trouble in some instances, but in these cases it is very likely that there is an insane temperament in the background. Anesthetics, too, may complicate the case by their effects upon various organs, which may combine with the other causes to produce a mental perturbation. Every anesthetic produces a more or less powerful depressing effect upon the heart. Cases are frequently recorded in which albuminuria has been discovered after chloroform and ether-anesthesia, the urine previously having been free from albumin. I have myself observed a hyperemia and torpidity of the liver, with febrile excitement and mental exaltation, following chloroform anesthesia. Chloroform and ether produce more or less anemia of the brain, or a venous stasis which may be very slow in being relieved; the patient may be feeble, and the delayed recovery from the effects of the anesthetic may end in confusional insanity. A very nervous person is liable to suffer from great dread of the operation, and often resists the anesthetic, or becomes wild and uncontrollable under the attempt to administer it. He often requires a greater quantity and it takes longer for him to become anesthetized, which has a more depressing effect. He remains for a greater length of time under its influence, and when he recovers from it labors under greater prostration; the shock is more profound, and prolonged nausea and vomiting may follow. He loses self-control, fears that he cannot recover, and, becoming absorbed in these thoughts with such intensity, in his already weakened nervous and physical condition, his mind gives way. From my researches, I learn that it is very rare for the patient to recover from the effects of the anesthetic with this mental disorder established, or evident to the observer; but it may come on suddenly or gradually within twenty-four, thirty-six, or forty-eight hours; or several days or weeks may elapse before its complete development. It is not always after a grave operation that these sequences occur. I have seen a violent outbreak in a patient from whom a small fatty tumor was removed. This patient, however, had had a previous attack of insanity.

---

[1] Read before the Southern Surgical and Gynecological Association at Nashville, Tenn., November 10, 1896.

There may be disease of some of the other organs, or their functions may be interfered with. The inebriate, and persons long addicted to the drug-habit, do not bear operations well, as a rule, and these conditions may be put down as predisposing causes of mental alienation after shock from surgical operation.

Savage of London read a paper before the British Medical Association, at its fifty-fifth annual meeting, in which he states that "in persons who are predisposed to insanity, intoxication with mineral, vegetable, or organic poisons, and the use of alcoholic or anesthetic inhalations, may be followed by acute delirious mania, from which the patient may recover or may lapse into dementia, or even to the progressive paralysis of the insane." Dent attempts to show that mental impressions may be produced in three ways: "by anticipation, by actual operation, and by after-effects." Mairet thinks, "first, that it is in those individuals who are predisposed by heredity or other grave causes—alcoholism, infectious diseases, etc.—that surgical operations give rise to insanity; second, in the constituent elements of an operation that might act on the brain were two most important factors, namely, the anesthetic, and the degree of surgical traumatism, with its after-effects, of which disturbed nutrition plays a very important part; and third, when predisposition also is considerable, the anesthetic alone may produce insanity, or it may result even after minor operations. It is, of course, necessary to take into consideration the mental state of the patient prior to the operation, especially in those graver ones where questions of life or death are frequently involved."

All diseases that have a tendency to exhaust or impair the nutrition of the nerve-centers weaken the mind and render it less able to withstand the great strain it may be called upon to sustain. Poorly fed, badly nourished subjects come under this head.

The antiseptic drugs used for dressing wounds have been accused of causing mental disturbance, but I have never seen a well-authenticated case from this cause. Septic absorption is sometimes an accompaniment, if not a cause. The mental derangement from septicemia, pure and simple, can, however, usually be differentiated from others.

The manifestations of mental disorders following surgical operations are not different from the same disorders produced by other causes. They usually occur in the form of confusional insanity, mania, and melancholia, while very rarely we may have paranoia and dementia. We can only classify the different manifestations of insanity by their symptoms.

The mind has a powerful influence over the functions of the organs of the body, which, in turn, when interfered with, will react upon the brain and nervous centers. The outbreak may be sudden, and may begin with wild delirium; more frequently it comes on gradually, showing itself as a delusion that cannot be dissipated, and this is followed by incoherent conversation. The patient becomes restless, and is troubled with insomnia. Impatience is succeeded perhaps by violent excitement, which passes beyond control except by the employment of absolute force; or there may be only fixed delusions and insomnia, which occur in many cases, and are often the first symptoms to attract attention to an abnormal condition of mind. On the other hand, the patient may become quiet, or morose, and refuse to speak, or to notice his surroundings. There may be a moderate rise in temperature, or it may be subnormal. In the violent form, there may be a higher temperature, increased pulse-rate, dry, coated tongue, loss of appetite, and impaired digestion and constipation, with more or less loss of physical power. Acute mania is generally accompanied in the beginning by febrile excitement. If the patient is violent and restless, and laboring under great nervous tension, the functions being all interfered with, the temperature is liable to rise with the excitement and fall with its subsidence.

In septic poisoning, and in the toxemias, we always have a greater or less degree of febrile movement. Sometimes after a violent outbreak, with continued excitement for several days, signs of exhaustion appear, and stupidity and coma gradually come on.

There can be no difficulty about the diagnosis of mental disturbance, or an attack of genuine insanity, after surgical operations; the manifestations are plain enough, but we cannot always be so positive about the classification of the trouble. It is not difficult either, as a general thing, to distinguish insanity from the delirium of septicemia, for while there are cases of insanity that are probably the result of septic poison, as has already been stated, they can generally be discriminated. The antecedent history is of value in these cases. If there be no hereditary history of insanity, nor a history of a previous attack, there being no organic disease present, and the subject being robust and of good constitution, the prospect for recovery of both mental and physical health is fair. If, however, there is an hereditary, or strongly neurotic tendency, and the patient is in feeble health, the danger is great. Digestive disturbances, feeble pulse, and a tendency to stupidity and coma are always very grave symptoms. The cases of so-called confusional insanity of some modern writers, when there is no organic disease, or septic complications, usually recover after certain lapse of time. Under these conditions the affection is entirely functional, and is not generally dangerous to life. Acute mania, if it does not exhaust the patient, is less unfavorable than melancholia; the former is rather more dangerous to life, while the latter tends to a permanent impairment of the mind. The percentage of recoveries from dementia is small.

The danger to life from insanity, after surgical operations, is probably greater than from any other cause, except malignant disease. My own experience, both from observation and study of a comparatively limited number of cases, has taught me that the prognosis is not very favorable, as a majority of the cases terminate in death, or permanent mental alienation. Any mental disturbance, coming on after a surgical operation, in a patient who had not suffered from a previous attack, I should look upon with apprehension. Those systems which are poisoned by chronic alcoholism, or by the use of drugs, do not seem to have the power of resistance that persons do who are free from the effects of these depressing influences. In view of the light we now have upon this subject, the knowledge gained from personal experience, and from the literature bearing upon it, it is the duty of the surgeon to have this unfortunate complication in mind whenever he decides to perform a surgical operation, whether it be a minor or major one. Cases of sufficient number are in evidence to prove the danger from even the most trivial operation, and he should always be on his guard. In obtaining the histories of our surgical cases, the antecedent mental and nervous peculiarities should be taken into account. We should be extremely careful and watchful of those patients upon whom we operate who have an hereditary tendency to insanity, and of those who are unusually nervous, and who submit to an operation with great dread and even protest. Careful preparation should be given them in the way of cheerful surroundings, reassuring conversation, nerve sedation, and plenty of sleep, before the operation. Urgent operations cannot be delayed, but the patient can be placed in the best possible physical and mental condition in the short time given for preparation. There are some operative cases in which every moment's delay is a menace to life, and the very best must be made of the surroundings. We should do what we can to fortify the patient with hope, and should calm his fears; should avoid making a great display of instruments in his presence, and avoid having too many in attendance. The anesthetic should be administered in a separate room from that in which the operation is to be performed, when this is practicable. When there is no special hurry much can be accomplished by gaining the confidence of the patient; make him even *anxious* for the operation. Prepare his system, and his mind, and relieve him of the great dread of the anesthetic. Impress those with whom he is in constant contact with the importance of cheerfulness in his presence, and with the necessity of keeping his mind from dwelling upon the ordeal through which he must pass. Encourage him to look forward to it as the only probable means of deliverance from his malady. Much can be done in this way to increase the powers of resistance to any complication that might arise. I believe that by such careful preparation we will be able in many cases to ward off this most unfortunate sequel.

CLINICAL MEMORANDUM.

A CASE OF DIPHTHERIA TREATED WITH ANTITOXIN; SUBSEQUENT DEATH FROM ACUTE ASCENDING PARALYSIS.

By G. M. WELLS, M.D., U.S.A.,
FORT MASON, CALIFORNIA.

On May 8, 1896, I was called to see a male child, eighteen months of age, suffering from diphtheria. He was a little below the average size, but had previously been healthy. At that time the temperature was 98° F.; pulse a little above 100, but quick and weak; respiration accelerated and shallow; appetite poor; bowels constipated; profuse acrid discharge from nose; faint, sweet odor from breath; glands about lower jaw enlarged, hard, and tender; both tonsils enlarged, with a dirty, grayish-white membrane covering them and the pillars of the fauces, a part of the soft palate, and the lower part of the uvula, and that part of the throat not covered with membrane was excessively red. During the next three days the case pursued a regular course, gradually growing worse, but the child continued to take a fair amount of nourishment. On the afternoon of the 11th the temperature was 101° F. and the pulse 160, weak, irregular, and thready. There was great exhaustion, and the color was bad. The bowels and bladder had been evacuated regularly and without difficulty. There was some difficulty in swallowing. The throat was very sensitive, and bled on the slightest touch. The tonsils were greatly enlarged, and there was great swelling and tenderness of the glands about the jaw and neck. The membrane had extended into the posterior nares, had covered almost all of the soft palate, and all of the throat as low as could be seen.

The discharge from the nose was profuse, thick, and tenacious, the odor exceedingly offensive, and caused extensive excoriation of the skin. At eight o'clock in the evening, just three days after I first saw the case, I injected between the scapulæ about 10 cubic centimeters of diphtheria-antitoxin containing 600 antitoxin immunizing units. No immediate effect followed the administration of the antitoxin, but on the 12th the child was much worse. The temperature remained about the same, and the heart-beats fell about twenty to the minute, but were so weak that the pulse could only be counted with the greatest difficulty. The condition of the throat and the glands around it remained about the same. At the point of inoculation there was a red spot three inches in diameter, slightly raised and indurated, but not tender nor painful. The color of the child was pale and ashen, and there were a marked stupor and inclination to sleep. On the 13th there was slight general improvement, and on the 16th the child was considered convalescent. Its temperature was normal; pulse was 135 to 140, but strong and full; throat was free from membrane; glands had softened, and were less tender; the color had changed; general appearance of the child was good.

The difficulty in swallowing passed away in a day or two, after which the child appeared to be well, except that it was thin, anemic, and a little weak. No examination of the urine was made, owing to the fact that a specimen could not be obtained. The local and antiseptic treatment of the case were far from satisfactory, owing to the age and irritability of the child.

There was no relapse, nor return of membrane. The child ate well, slept well, ran and played around the house, was bright and cheerful, and seemed to have made a full and complete recovery, and was so reported on the 25th of the month.

About the 1st of June it was noticed that there was some difficulty in walking, and that the child would fall down without any apparent reason. On the 3d it was brought to me, and a careful examination showed paresis of the left lower extremity. This was most marked in the flexor muscles of the thigh, and extensor muscles of the leg. The entire limb was dragged after its fellow, and the toes hung downward. The step with this leg was always shorter than with the other, and it showed signs of weakness each time the weight of the body was thrown upon it. It was further noticed that the child was more liable to fall down when the weight of the body rested on this leg. The child suffered no pain, and was gaining in weight. Actual paralysis took the place of paresis, and gradually extended upward. The trouble soon manifested itself on the right side, and the paralysis was as complete there as on the opposite side. After a day or two the child would not make any attempt to walk or stand alone, and later the limbs hung perfectly limp, and could not be moved at all by the child.

The muscles of the back became involved, and then those of the neck. At first there was difficulty in sitting alone, and the child wanted to be supported in its mother's arms; while later it had to lie down all the time, could not turn over, nor raise its head.

Several days after the paralysis was noticed in the lower extremities, the soft palate became involved again; slightly at first, but later with sufficient severity to cause some regurgitation of liquids, and difficulty in swallowing. There was the nasal twang common to such cases, and some hoarseness as well.

The upper extremities did not become weak until very late in the course of the disease, and it was believed at the time that they were not involved in the paralytic process, and I have had no reason to change my opinion since. The child gradually grew worse until the afternoon of June 13th, when it died without a struggle of any kind. It had a good appetite during its last illness, and took a fair amount of food up to the day of its death. Its digestion was good, it did not lose in weight, and its bowels moved naturally and regularly each day. Although it experienced considerable difficulty in swallowing, it took plenty of liquid in the form of milk and water, and urinated at regular intervals. There was no indication that either the rectum or bladder was affected at any time. Vision was apparently not affected, and both pupils were of the same size and responded to light. The child could talk, though with some effort, until a short time before it died, and it retained consciousness almost to the last. Respiration was natural until a day or two before death, when it became more rapid, shallow, and labored.

There were no indications of disease in either lung. The color of the skin had improved much after the first illness, and remained fairly good until the day before the child died. It then became dark and livid, and assumed a mottled appearance just before respiration stopped. The heart showed signs of weakness after the first few days, which steadily increased to the last. The pulse ran up from a little more than 100 to about 200 to the minute and became so weak that it was often impossible to count. Any movement or irritation of the child would greatly accelerate the pulse, which would become quick and intermittent, showing the irritable condition of the heart. The heart-beat was so weak that it was inaudible, and the pulse could not be counted for some time before respiration ceased, showing that death was the result of cardiac paralysis. The temperature of the child varied but little, and was not above normal at any time. Most of the time it was between 98° and 98.5° F., but one or two times it was a trifle below 98° F. There were no chills, and at no time was the surface of the body covered with perspiration. The child often looked as if it were cold, and required a large amount of clothing. The hands and feet were cold most of the time in spite of all efforts to keep them warm. There was no edema in any part of the body, and nothing to indicate that the kidneys were affected, although, as stated above, I was unable to procure a specimen of urine for examination. Although motion was paralyzed in the greater part of the body, sensation remained normal, and the sense of touch, as well as that of pain, was present up to the time of death. Unfortunately the reflexes were not tested, nor electricity applied, and as no autopsy was made the exact pathological condition was not ascertained. From the literature at my command I find that acute ascending paralysis is a comparatively rare affection, and as the present case occurred in a child which had previously been treated with antitoxin for the cure of diphtheria, a double interest attaches to it. The exact causation of the paralysis is a question that may be answered more satisfactorily after the antitoxin-treatment shall have been more extensively used and better understood. Of one thing, however, I feel sure, and that is: No beneficial effect followed the administration of the antitoxin. It might have been administered too late in the disease to give it a fair trial, or it may have been administered at a time when the child would get worse irrespective of what treatment might be used, but the fact remains that the child was much worse during the next twenty-four to thirty-six hours than it had been before, and it was not until the end of forty-eight hours that any marked improvement could be noted.

MEDICAL PROGRESS.

An Unusual Case of Lockjaw.—SACHSE reported in the *Centralbl. f. Chir.*, No. 40, 1896, an unusual case of lockjaw occurring without known cause in a male, aged twenty-four years. On waking one morning he found he could not open his mouth as far as usual. The disability increased daily, until he was unable to separate his teeth. For four years he was treated without benefit, until it was discovered that the right upper wisdom-tooth pointed directly outward, and so pressed against the internal pterygoid muscle as to prevent the jaw from opening. It was removed with difficulty. Immediately after its extraction the jaw could be partially opened, and in eight weeks function was fully restored.

Regeneration of the Axis-cylinders of Divided Peripheral Nerves.—ZIEGLER has published in the *Archiv f. klin. Chir.*, vol. li, part 4 (abstract in *Centralbl. f. Chir.*, No. 46, 1896) an account of his laborious investigations into the subject of regeneration of divided nerves in dogs, rabbits, rats, and frogs. According to most histologists and embryologists, an active growth from the divided ends of the axis-cylinder ushers in the regeneration of the cut nerve. Ziegler claims, on the contrary, that the old axis-cylinder plays merely a passive part, and that the real regeneration is a neuroplasma rich in nuclei, which sends out protoplasmic fibrillæ, which later become differentiated into axis-cylinders and the other essential components of a nerve.

After division or constriction of a nerve, degeneration takes place in its peripheral and, to a less extent, in its central end. This degeneration is really a vital act, and predisposes to the absorption of the material of the degenerated fiber; meanwhile the sheath of Schwann—the neurilemma—is stimulated to active growth, and from this springs the protoplasm rich in cells, which absorbs the degenerated fibers, and by the growth and differentiation of which the new nerve is formed. This sheath of Schwann cannot, therefore, says Ziegler, be of connective-tissue origin and nature.

The formation of new nerve-fiber takes place only in the central stump of the divided nerve, in intimate connection with the border of the degenerated area; and the union of an old fiber with a new one is accomplished by means of a nucleated drop of protoplasm, which appears in the end of the old nerve-fiber in close association with the sheath of Schwann.

The differentiation in the new protoplasmic strings appears early. First, as the finer fibers are recognizable, the axis-cylinder makes its appearance. Sometimes two or three of them appear side by side in a single fiber. Their union with the old axis-cylinders is a *secondary* process. After the axis-cylinder appears in the new protoplasm, the medullary sheath becomes differentiated about it, and the nuclei assume a more superficial position, giving the appearance of a surrounding membrane to the newly formed fiber. This grows thinner and becomes the sheath of Schwann.

Experimental Results with Antistreptococcic Serum.—PETRUSCHKY, who reports in *La Presse Medicale*, November 11, 1896, his experiments with cultures of streptococci and an antistreptococcic serum, sent to him by Marmorek, has not obtained the same promising results which that investigator reported. In the first place, he found that a dose stated by Marmorek to be absolutely fatal, killed his rabbits only exceptionally. In fact, two of his own cultures of streptococci, which he had grown for two years, proved to be more virulent, so that their actions were not checked by antistreptococcic serum, although the latter was injected within twenty-four hours of the time of infection. The author, under the circumstances, thinks he is justified in his conclusions: First, that the therapeutic action of the serum is not yet to be recommended in man; and second, that up to the present time there is no certain proof of the possibility of serum-therapy in streptococcic infection.

Chronic Obstruction Produced by a Sharp Bend in the Sigmoid Flexure.—FREY reports an unusual case of chronic intestinal obstruction in *Beit. z. klin. Chir.*, vol. xvii, p. 123. The patient, a young man of twenty, and ill-developed, suffered for eight years with oft-recurring attacks of intestinal obstruction. An attack began with pain and swelling of the abdomen, which was relieved by the passage of wind. In a few days all symptoms disappeared. There were usually alternate constipation and diarrhea. In the course of time, the enlargement of the abdomen became permanent. Besides this dilated abdomen, it was noticeable that twenty inches of a rectal tube passed easily into the bowel, which received, without disturbance, two quarts of water. Peristaltic action could be seen in a large portion of bowel lying across the upper part of the abdomen. This was undoubtedly transverse colon, and the obstruction was considered to be in the descending colon.

At laparotomy, the sigmoid was found to be greatly dilated, presenting somewhat the appearance of a stomach (the sides being reversed), and at the point corresponding to the pylorus there was a sharp bend where the sigmoid entered the rectum, so that a sort of valve was formed, which could be closed by distension of the sigmoid flexure. Four inches of bowel, including the sharp bend, were removed, and a lateral entero-anostomosis was performed. In two months the circumference at the umbilicus had decreased from 81 cm. to 65 cm., although there was no loss of weight.

Several similar cases have been reported, and also cases in which dilatation of the sigmoid flexure had caused symptoms of chronic obstruction.

Frey admits that in the present state of our knowledge a differential diagnosis between these conditions and volvulus is impossible, for the symptoms in each are merely those of temporary or incomplete obstruction. In cases of acute complete obstruction, the trouble is almost certainly due to volvulus.

The Origin of a Ganglion.—The claim which Ledderhose advanced in 1893, that ganglia are cystomata arising in para-articular tissue by gelatinous degeneration, and that large cysts are formed by the union of small ones, while not explaining all the difficulties connected with this obscure subject, nevertheless seems to stand the test of time. The latest evidence in support of this theory is brought forward by THORN in the *Archiv f. klin. Chir.*, vol. lii, p. 593. His microscopic examination of numerous specimens conforms, in general, to that of Ledderhose. He also reports an interesting case in which a small tumor, presumably a ganglion, was cut down upon. The tumor was situated upon the radial side of the back of the hand, and moved with the tendon of the extensor communis digitorum running to the index-finger. When the sheath of the tendon had been opened, it was seen that a small cyst existed in the substance of the tendon, and which, in its contents and the character of its wall, presented macroscopically the appearance of a ganglion. Microscopically, it was plainly a gelatinous degeneration of the tendon. It appeared almost certain that if left to itself this cyst would have ruptured into the tendon-sheath.

Mortality in Diphtheria of Less than One Per Cent.—NEUMAYER (*Centralbl. f. Inner. Med.*, 1896, No. 44) reports that he has treated, since 1880, 977 cases of diphtheria, with only six deaths, a mortality of 0.6 per cent. The treatment consisted in gargling, irrigating and swabbing with the following solution:

Potassium chlorate, ...	℥ ss
Lime water, ...	℥ vi
Decoction of marsh mallow, . . .	℥ xxv

For use (every hour or every two hours), a few spoonfuls are diluted with three or four times as much hot water.

By employment of this treatment, according to Neumayer, the fever falls, comfort is felt, and a striking demarcation of the diseased portions appears and the further spread of the inflammation is prevented. His theory of the treatment is that the gargle coagulates the exudates and infiltrates, thus fixing their toxins, which are oxydized and rendered harmless by the potassium chlorate.

THERAPEUTIC NOTES.

Double Pointed Tacks for Sutures.—A novel substitute for a suture in skin incisions is recommended by WACHSMANN in the *Berl. klin. Woch.*, November 9, 1896. It is neither more nor less than a double pointed tack, such as is used to nail matting to the floor. The points are made short, about one-quarter inch long, and are slightly bent toward the center so as to prevent their slipping out. It is claimed that they can be applied in about one-quarter of the time required for a suture. They are made of fine steel wire and nickel plated. They can be sterilized in any manner, and may be left in the skin ten days if necessary without setting up any irritation.

Methylene Blue for Headache.—This substance which, on account of its intense coloring properties, has not become as popular as its analgesic virtues warrant, has found in LEWY an enthusiastic advocate. In the *Berl. klin. Woch.*, November 9, 1896, he speaks of the great success he has had with it in migraine. Through its very favorable action he has been able to relieve pain which defied all treatment, and to relieve it not temporarily but permanently. In order to avoid the vesical irritation which sometimes follows if this drug is given alone, it is prescribed in powders of one or two grains, together with an equal quantity of powdered nutmeg, administered in a capsule of which three or four a day are to be taken. It is necessary to caution the patient that the urine will become a deep blue color. This occurs within thirty minutes after the capsule is swallowed, and continues for eight to ten days.

Lewy's most marked successes have been in cases of angio-spastic migraine, and in nervous and neuresthenic headaches, and the results have been such that he speaks of the action of methyl blue as a curative, and not a palliative one.

Serum Diagnostic Test in the Fetus.—APERT (*La Med. moderne*, November 11, 1896) applied to the fetus the serum test for typhoid fever in the case of a woman suffering from that disease, and who, in consequence, aborted at the third month. Sterile fluids, taken from various parts of the body of the fetus, had no effect upon growing cultures of the typhoid bacilli. On the other hand, ten drops of macerated placenta, added to ten drops of the culture, produced a characteristic balling up of the bacilli.

Tincture of Horse-chestnut for Hemorrhoids.—ARTAULT of Vevey, Switzerland, prescribes tincture of horse-chestnut, in doses of from 20 to 30 drops, twice daily, in hemorrhoids, and claims it to be a specific.

Phosphate of Soda in Exophthalmic Goiter.—TRACHEWSKI, Kocher's assistant, extols the use of phosphate of soda in the treatment of exophthalmic goiter. He prescribes it in doses of from 25 to 40 grains daily.

Collodion in Pruritus Ani.—SAMWAYS of Mentone claims great success in the treatment of pruritus ani and hemorrhoids from painting the surfaces thoroughly with collodion.

THE MEDICAL NEWS.

A WEEKLY JOURNAL
OF MEDICAL SCIENCE.

COMMUNICATIONS are invited from all parts of the world. Original articles contributed *exclusively* to THE MEDICAL NEWS will after publication be liberally paid for (accounts being rendered quarterly), or 250 reprints will be furnished in place of other remuneration. When necessary to elucidate the text, illustrations will be engraved from drawings or photographs furnished by the author. Manuscripts should be typewritten.

Address the Editor: J. RIDDLE GOFFE, M.D.,
No. 111 FIFTH AVENUE (corner of 18th St.), NEW YORK.

SATURDAY, JANUARY 9, 1897.

THE PREVENTION OF TUBERCULOSIS.

IN these days, which almost merit the name of the germ age, when timid reading people would, if they could, have even the air they breathe sterilized, the article by Dr. Holt, on "Tuberculosis in Infancy and Childhood," in the MEDICAL NEWS, December 12th, comes almost like a benediction.

The knowledge of the infectious nature of tuberculosis, and its dependence upon a germ, has led caretakers of infants to sterilize almost everything that goes into a child's stomach, sometimes greatly to the detriment of the child's digestion and nutrition.

The evidence adduced seems conclusive that tubercular infection is very rarely produced by alimentary ingesta, and that many of our precautions, so far as tuberculosis is concerned, have been unnecessary, while the real problem of prevention remains unsolved.

Among 119 autopsies on tuberculous children, 66 per cent. of whom were under two years of age, Dr. Holt found that the lungs showed tubercular lesions in 99 per cent., and the bronchial glands in 96 per cent., while in only 37 per cent. were the intestines and in 4 per cent. the stomach the seat of the disease. The lesions of the alimentary tract, when extensive, were almost invariably associated with extensive pulmonary lesions, and were generally secondary to them.

The deductions from his extensive and scientific pathologic observations are, that primary tubercular infection of the alimentary tract is of extreme rarity, and that this rarity is due partly to the power of the tract to repel, pass on and expel the germs, if ingested, but more largely to the fact that the milk of tuberculous animals is seldom infected and their flesh more rarely still. This observation, if true, and there is no reason to doubt it, is of vast importance, as it removes one of the reasons which have been urged for the sterilization of milk.

While it relieves our minds on one point, it should serve to sharpen our wits to devise methods of preventing infection through the respiratory tract. As is stated, "It is by breathing an atmosphere containing tubercle bacilli that most infants get the disease," and this knowledge brings disagreeably to our consciences the fact that we have hardly made a beginning toward the prevention of tuberculosis. Optimists as we may be, hardly a glimmer of hope is afforded by any plan except a strict quarantine of the tuberculous, including a destruction by fire of all secretions or other vehicles of infection. If a poor, inoffensive leper is known to be at large the people of a whole city shudder with fright and clamor for his confinement, compared to which death would be preferable; but, toward a disease much more infectious than leprosy, and of which about 6000 people die yearly in New York City, the laity are totally indifferent, and the medical profession, as a body, still apathetic.

A persistent and diplomatic campaign of education may do something in the way of prevention, but tuberculosis is on the increase where it has always existed, and has appeared where formerly it was unknown. It has only recently transpired that regions like Colorado and Southern California, where tuberculosis was formerly unheard of, and whose climatic conditions have, in recent years, attracted hordes of tuberculous people, have become infected and now offer no immunity even to natives. This transformation, in the light of our present knowledge, is due to a contamination of that previously pure air by imported infectious material.

If whole regions can be thus infected, how much easier can public conveyances, public thoroughfares, places of entertainment and worship, workshop and salesroom, hostelry and private house, become the scene of abiding infection. Much would be accomplished if the laity could be brought to a realizing sense of the infectiousness of the sputum; but that is only the first step, and, sooner or later, it will transpire that only by a rigid quarantine can the disease be checked. By no known human means can it be stamped out.

THE ANTISEPTIC VALUE OF IODOFORM.

In spite of the published statements of such well-known surgeons and bacteriologists as Heyn, Rovsing, de Ruyter, Sänger, Neisser, Baumgarten, and König regarding the antiseptic value of iodoform—they having rejected it as possessing no germicidal properties whatever—it has continued to be used by almost every surgeon, and the clinical results obtained from its use are, on the whole, excellent. Indeed, if this were not the case the surgeon would not consent to defile himself, his clothes, his house, and his patients with it. Frequently-repeated experiments have proved beyond a doubt that germs of all sorts grow with their wonted vigor in close proximity to grains of iodoform powder, and it has even been said that they will multiply in the powder itself, though that is, of course, impossible, unless some nutrient material is combined with it. As a consequence, this discrepancy between bacteriological and clinical testimony has, up to the present time, remained one of the riddles of medicine, but it has apparently been solved by Lomry, an assistant at the Löwen University. The details of his work were recently published in the *Archiv. für klin. Chir.*, vol. liii., p. 787.

His first series of experiments with iodoform were to determine its action upon suppurating wounds. A number of dogs and rabbits were selected for the test, the flanks of each animal being shaved and disinfected, and a wound made into the muscular tissues on each side. Both wounds were then injected with staphylococci. Iodoform powder was introduced into one wound, but not into the other, and both wounds were covered with aseptic dressings. The wounds were inspected daily, and numerous microscopic and bacteriologic tests were made. In all, twelve dogs and six rabbits were experimented upon. In every case the iodoform gave to the wound to which it had been applied, a red, healthy appearance, which was lacking in the wound of the opposite side. The iodoform reduced the amount of secretion, increased the diapedesis of the white blood corpuscles, and did not diminish their vitality, as shown by their ameboid movements; it favored cicatrization, and, finally, which really includes all the foregoing, it delayed the development of the microbes. In other words, these experiments proved, as far as experiments upon animals can prove, the correctness of the clinical experience with the drug.

Lomry next repeated the laboratory tests with iodoform in the manner practised by bacteriologists—with gelatin, agar, and bouillon cultures—and found, just as others had found, that it had practically no effect in delaying the growth of microbes. But the surface of a wound does not present the same conditions as does nutrient gelatin in a test-tube; the iodoform disappears, to a certain extent, from the former, while it does not from the culture medium, so the thought was suggested that iodoform might be soluble in a wound, and hence its antiseptic action. It is insoluble in gelatin, agar, and bouillon, and in these culture media it is inert. It is, however, soluble, to a certain extent, in serum, hydrocele fluid, and the like, and the theory was entertained that if the culture medium contained a considerable proportion of serum, iodoform would restrain the development of germs in it exactly as it does in wounds. With this theory in mind, numerous experiments were carried out with serum obtained from the blood of the horse, dog, and rabbit, and with the fluid from hydroceles, blisters, pleurisy, and abscesses in man, and in every instance the result was the same, *viz.*, the cultures in the medium in which iodoform was employed grew much less rapidly than those in which there was no iodoform.

It is to be noticed, however, that this antiseptic action of iodoform is a weak one, and that in no case did it altogether prevent the development of the bacteria.

The natural course of infection in a wound may be hindered by iodoform, then, in three ways: (*a*) By limiting the development of the microbes; (*b*) by lessening their virulence; and (*c*) by neutralizing their toxins.

In another series of experiments, infected serum, with and without iodoform, was injected into rabbits. The results were analagous to those obtained in test-tubes. If a certain amount, say one-quarter of a cubic centimeter, of a given sero-bouillon culture of staphylococcus was sufficient to kill a small rabbit in sixteen hours, the same amount of culture with iodoform would prove fatal only after the lapse of twenty-four hours. Here, again, the difference was one of degree only, though by careful work it was found possible to determine the dose of culture which would kill without the admixture of iodoform, but would not kill with it.

Similar experiments made with the filtered toxins of pyogenic microbes (diphtheria and tetanus bacilli, and bacteria coli commune) gave like results, so that the iodoform may be said to have an antitoxic action, although it is by no means a complete one. The fact may be accepted, therefore, that iodoform is an antiseptic, and that it acts in the manner above suggested, although Lomry does not attempt to explain it. The so-called solution in serum, in fact, does not appear to be an ordinary solution at all. After being filtered, dried, and pulverized, and treated for a long time with ether, and then distilled, not a trace of iodoform or iodin could be detected in the distillate, although the residue gave a strong iodin reaction.

However, the first question is not, How does iodoform act?, but, Has it a real, even though weak, antiseptic action?, and this seems to have been answered beyond a doubt by this thorough series of experiments.

ECHOES AND NEWS.

An Italian Honor.—The Italian government has bestowed on Dr. Behring of Paris the honor of Grand Cordon of the Crown of Italy, in recognition of his discovery of the antidiphtheritic serum.

Sir Joseph Lister a Peer.—One of the chief interests in the New Year's honors is the peerage bestowed upon Sir Joseph Lister, who is the first medical practitioner called as such to the House of Lords.

British Medical Association Meeting at Montreal in 1897. The Montreal people have determined to build a temporary large hall on the grounds of the McGill University to supplement the other buildings upon the campus. This special building will be chiefly used as a reception room and business office, in order to avoid the overcrowding that has formerly been a drawback and source of confusion. Twelve college buildings will be thrown open to the meetings of the twelve sections.

Alumni of Mt. Sinai Hospital.—The associated alumni of Mt. Sinai Hospital, New York, have elected these officers: President, Dr. Albert H. Fridenberg; vice-president, Dr. Richard H. Cunningham: secretary, Dr. Martin W. Ware; treasurer, Dr. Edwin Sternberger.

College of Physicians and Surgeons, New York.—The *Bulletin* of Columbia University for December states that the serious illness of Professor Peabody has incapacitated him from giving his lectures in therapeutics and materia medica, though it is hoped that he will be able to resume his work early in 1897. His place has been filled by Dr. Henry A. Griffin, who graduated at the College of Physicians and Surgeons in 1889.

Death of Dr. Pancoast.—Professor William H. Pancoast, the distinguished physician and surgeon, died at his home in Philadelphia, January 4, 1897, aged sixty-four years. He was the son of the famous surgeon, Joseph Pancoast, and was born in Philadelphia on the 16th of October, 1835. He was graduated in the Jefferson Medical College in 1856, and afterwards studied for three years in London, Paris, and Vienna. On his return to this country, he established himself in practice in Philadelphia, and soon acquired a high reputation as a bold, rapid, and skilful operative surgeon, who was seldom mistaken in his diagnosis and was always conservative in his treatment. He served as a surgeon in the army during the Civil War. In 1874, he was elected to succeed his father as professor in the Jefferson Medical College. He became professor of the Philadelphia Medico-Chirurgical College in 1886.

The Trained Nurses of America Organize.—Under the name of the "Trained Nurses United Aid Society of America" the most extensive association of nurses yet organized in this country has been recently incorporated. The movement, as enlarged, is in the interest of no less than 6000 trained nurses now finding employment in this country. The object of the society is the relief of members whose professional activity is suspended on account of illness or accident, and in case of death the payment of a funeral benefit. Such advantages also are proposed as homes of rest, loans of money in case of temporary distress, a sickness fund, endowed beds, and pensions.

The Fly as a Carrier of Bacilli.—Hoffman has demonstrated the presence of the tubercle bacillus in the bodies of flies taken in a room occupied by a consumptive. The droppings of the flies were full of bacilli, which were shown by experiment to be fully virulent. Coppen-Jones has proved by means of chromogenic bacteria that infection can be, and actually is carried, not only in the bodies of flies, but also by their feet. In one experiment cultures of the bacilli prodigiosus were mixed with tuberculous sputum. Flies which had been in contact with this mixture were permitted to walk across the surface of sterilized potatoes. In forty-eight hours numerous colonies of the bacillus prodigiosus were visible.

Prizes for Advances in Science.—A fund estimated to be nearly $10,000,000 has been devoted to the cause of science by the will of the late Alfred Nobel, the Swedish engineer and chemist, of Stockholm. The proceeds of this handsome sum will be divided equally into five prizes, to be awarded annually. Three of the prizes will be for the greatest discovery in physics, the greatest discovery in chemistry, and the greatest discovery in physiology or medicine. The fourth prize will be for the most notable literary contribution on physiology or medicine, and the fifth for the greatest achievement for the promotion of peace. The competition for these prizes will be open to the world.

Russian Expenditures for Hygienic Purposes.—The Russian government has just published some figures which give an idea of the considerable sums that Russia consecrates to hygiene and medicine. These figures bear upon thirty-four governments of European Russia where the system of the *Zemstros* prevails. The *Zemstros* are the local committees of government analagous to the French municipal or general councils. These committees have in their jurisdictions free medical assistance in hygienic affairs. In 1895 the expenses depending on these two objects came to the sum of eighteen million roubles, about fifty millions of francs, whereas the total expenditure was sixty-six millions of roubles, or about 175 millions of of francs. Medical and hygienic assistance have thus absorbed about a third of the sum spent.

Dr. Theodore G. Wormley Dead.—Dr. Theodore G. Wormley, the distinguished chemist and toxicologist, and professor of these branches in the medical department of the University of Pennsylvania, died on the 3d inst. of stomach trouble, after an illness of several months. He was born in Wormleysburg, Pa., on April 1, 1826, educated at Dickinson College, and in 1849 was graduated in medicine from the Philadelphia Medical College. In 1852 he was called to the chair of chemistry and natural sciences at Capitol University, Columbus, Ohio, which he held until 1865, and was also professor of chemistry and toxicology in Sterling Medical College from 1854 to 1877. In 1877 he was called to the chair of chemistry and toxicology in the medical department of the University of Pennsylvania, which he has since held.

The Pennsylvania State Board of Medical Examiners.—The rapidly increasing standard required by this board is an encouraging indication of progress toward the general elevation of scientific medicine in America. Nearly thirty-eight per cent. of the applicants were rejected by the board at its December meeting, while the percentage of failures in July last was only fifteen. Bacteriology is said to have been the subject upon which many showed an insufficient knowledge. The scope of each examination is intentionally broadened, and a more varied, as well as a more precise acquaintance with all departments relating to practical medicine, will be exacted at each succeeding session of examiners. While sympathy might be felt for those who fail, congratulation for the worthy should be extended by all who have the glory and honor of the profession at heart.

Yersin's Anti-plague Serum.—Dr. Monod, a prominent health official at Paris, has communicated the following in the Académie de Médicine: The French consul at Haïphong writes that M. Chausse treated by injection two students who had been stricken by the bubonic plague, and cured them both. Dr. Yersin, during ten days at Amoy,, obtained twenty cures of bubonic plague out of twenty-two cases treated by means of subcutaneous injections of serum from the Pasteur Institution. The efficacy of the Yersin serum as a cure for bubonic plague may now be regarded as a scientifically demonstrated fact. It follows that by organizing a sufficient supply of serum it ought to be possible, provided the Chinese government takes the necessary steps, to cause the disappearance of the bubonic plague from the regions in China where the horrible malady is endemic.

Fees of Austrian Professors.—Everyone knows that in the German universities the professor is paid by his students, and that his fees represent the greatest part of his benefits. The Austrian government, notwithstanding the resistance of the majority of doctors, has just decided to modify this state of things by presenting a bill which regulates the salary of the professors of a university. This bill suppresses the fees of students to professors and allots the payment of professors directly to the government. Students will not pay less but they will pay to the government and not the professors. This is the French system. The professors who teach abstract matters (*théoriques*) and who have small audiences will profit by this change, but others, and particularly professors of clinics, who have from three to four hundred students, will see their revenues considerably diminished. It is to be feared that these professors will no longer hesitate to respond to calls from German universities, and on the other hand that German professors will refuse henceforth to accept a chair in an Austrian university. The new law would be fatal to the old fame of the medical school of Vienna.—*Méd. Moderne.*

Surgery and Vivisection.—A curious instance of the direct application of vivisection to practical surgery was related to the Linnean Society, by Mr. J. D. Middleton. It is the custom in Smyrna to heal wounds by the help of ants. A friend of Mr. Middleton received a severe but clean cut on the forehead. He went to a Greek barber to have the wound dressed, and the barber employed at least ten living ants to bite the two sides together. Pressing the margins of the cut with the fingers of the left hand, he applied the insect by means of a pair of forceps held in the right hand. The mandibles of the ant were widely open for self-defence, and as the insect was carefully brought near the wound, it seized upon the raised surface, penetrated the skin on both sides, and remained tenaciously fixed while the operator severed the head from the thorax, so leaving the mandibles grasping the wound. The same operation was repeated until about ten ants' heads were fixed on the wound, and left in position for three days, or thereabouts, when the cut was healed and the heads removed. Sir John Lubbock, in his work on "Ants, Bees, and Wasps," quotes from M. Mocquerys a passage which relates that the Indians of Brazil made use of this procedure in the case of wounds. He had often seen natives with wounds in course of healing with the assistance of seven or eight ants' heads. This surgical ant is the *Atta cephalotes* (Linn).—*The Scalpel*, December.

The Commissioners of Charities and the Hospital Question. At the last meeting of the Medical Society of the County of New York the following preamble and resolutions were proposed and adopted:

WHEREAS, During the year 1895 the previous Board of Commissioners of Charities dismissed the members of the medical staffs of the City, Fordham, Gouverneur, Randall's Island, Workhouse, Almshouse, Maternity, and Nervous Diseases Hospitals, replacing them by nominees of the three medical schools of this city, to wit: the College of Physicians and Surgeons, the University Medical College, and the Bellevue Hospital Medical College; and

WHEREAS, The Commissioners of Charities have not rectified the injustice done by their predecessors during the past year, notwithstanding that frequent and repeated petitions have been made to them so to do; and

WHEREAS, The medical profession is satisfied that no permanent or equitable arrangement can be arrived at under the present condition of affairs, and that, if matters are left in their present condition, these positions will be a continued source of ill-feeling in the profession and of annoyance to the commissioners; therefore, be it

Resolved, That it is the opinion of the Medical Society of the County of New York, as the legal representative of the medical profession of this county, that all medical positions, salaried as well as unsalaried, which are within the present gift of the Commissioners of Charities, be taken away from said Commissioners and from the medical colleges and be placed under the control of the municipal civil service of the City and County of New York, to the end that fitness and merit, and not political nor collegiate favoritism, shall be the tests for appointment in the medical positions of the municipal service; and be it further

Resolved, That this resolution be referred to the Comitia Minora of the Medical Society of the County of New York, with instructions to draft a bill for presentation to the Legislature at an early moment, and to consult or coöperate with any body or bodies that it may think proper to secure the objects proposed by this resolution.

Obituary.—Dr. Jacob T. Field, of Bayonne, N. J., died November 24th. He was born at North Branch, Somerset County, N. J., in 1839, and was a graduate of Rutgers College and the College of Physicians and Surgeons of New York, class of 1863. He served in the United States navy with distinction during the war, and was honorably discharged from the service. With the late Dr. Frederick G. Payne, he founded the Bayonne City Hospital. He was a skilful surgeon with a large practice, and had practised his profession in Bayonne for more than thirty years. His wife and one son, Dr. Frank L. Field, survive him. —Dr. William Wallace, who died in Brooklyn on the 22d ult., was a man of special prominence in charitable and educational work, as well as having an extensive practice. Among the institutions with which he was associated were the Long Island College Hospital and Dispensary, St. John's and St. Mary's Hospitals, and the Home for Consumptives, the Church Charity Foundation, and the Vestry of St. Ann's-on-the-Heights. He was ex-president of the Pathological Society. He was a native of Cork, Ireland, having been born there sixty-one years ago. He held a double qualification from the Royal Colleges of Scotland in 1855 and 1860. He was an assistant surgeon in the naval service during the Crimean war. He settled in Brooklyn in 1864, and straightway became enlisted in all the honorable departments of work that signalize our profession. His final illness was locomotor ataxia, from which he suffered for about six months. His wife and two sons, one of the latter a graduate in medicine, survive him.

CORRESPONDENCE.

GUAIACOL IN RHUS-POISONING.

To the Editor of the MEDICAL NEWS:

DEAR SIR: August 16th last I was called to see a patient, male, aged forty-five years, suffering from an aggravated form of rhus-poisoning, the face being swollen to such an extent as to wholly obliterate the features, and the eyes being entirely closed. I made an application of zinc-oxid ointment, and ordered applications of carbonate of sodium ʒ ii in aqua ℥ iii on absorbent cotton. Result negative. Third day after onset I made an application of pure guaiacol, freely painting it over the inflamed area with a camel's-hair brush, and then covering the parts.

Next day there was marked amelioration of the trouble, and on the fourth day after inaugurating the guaiacol treatment, the poisoning and its resulting inflammation had entirely disappeared.

Again, on October 7th, I was called to treat a boy of eleven years with the same trouble, one side of the face and neck being affected to about the same extent as the previous case. I used the same treatment as before, *viz.*, guaiacol, and on the second day thereafter he was out and at school, the trouble having entirely abated.

Some two years ago I was led to try this drug in the treatment of erysipelas, having received a monograph on the subject from Dr. C. J. Whalen of Chicago, and with good results, which was my reason for experimenting with it in the above two cases of rhus-poisoning.

Of course, these being the only cases in which I have had an opportunity of using this treatment, it would be premature to claim the guaiacol a specific; yet it certainly seems to have been of good service.

E. K. MORRIS, M.D.

STURGEON BAY, WIS.,
December 26, 1896.

The Paris Night Medical Service.—According to *Médecine Moderne*, the public night medical service of Paris is maintained at a cost to the city annually of 145.000 francs, or about $29,000. In return for this service the patients paid the city but 3217 francs. One hundred and thirty-five doctors are employed, the yearly salary of each being 600 francs, or $120.

OUR PARIS LETTER.

[From our Special Correspondent.]

PROFESSOR ROUX TALKS ON DIPHTHERIA—PET ANIMALS AS DISSEMINATORS OF DISEASE—TWELVE FATAL CASES OF "PSITTACOSIS"—TUBERCULOSIS IN DOGS—"WOMEN AND THE CRUSADE AGAINST PROSTITUTION, VIVISECTION, ALCOHOLISM, AND WAR."

Paris, December 14, 1896.

On December 11th and 12th Professor Roux talked before his special students at the Pasteur Institute on diphtheria. Needless to say the lectures were extremely interesting and complete. The review of the recent work on diphtheria the world over was made a special feature. Though the talks lasted over four hours altogether, not once did the speaker mention the Pasteur Institute or his own work. Behring's investigations were given a large place. The recent work of Brieger and Boes was fully recalled, and Ehrlich, Sydney Martin, and our own Park, Williams, and Talbot Smith, received mention. Only that certain important lacunæ in our knowledge of diphtheria were filled up, without the mention of any names, one would not know how much Yersin and Roux had done on that subject. Metschnikow, in treating of cholera, had displayed the same modesty. There was a casual mention of a personal experiment in swallowing a certain amount of a living culture, and that was all there was to show that he had ever done any special work in the study of the disease. Thus, it would seem, the traditions of the Pasteur Institute are being lived up to, and the modest spirit of the great master is perpetuating itself in his pupils, and in the atmosphere of the Institute where rest his remains. Such self-abnegation is delightfully refreshing in these days of savants who are usually thoroughly immune to the microbe of excessive modesty.

Roux finds so far that none of the objections urged against the serum is well founded. The serum does not sensibly affect the normal individual even when injected in considerable quantities: it does not produce nephritis; it gives rise to no rashes other than those which any serum may occasion, and it has now been used in too many thousand cases to leave at all uncertain its absolute innocuousness, even though its administration is sometimes accompanied by various pathologic phenomena, of which, however, it is not the cause. The doubting Thomases in serumtherapy would find serious matter for thought in his enthusiastic hopefulness. He urges the early use of the serum, as soon as the slightest patch of membrane is visible, and without waiting for the result of cultures, and insists on its liberal injection. Not 5 or 10 units, but hundreds, even thousands, may be used in serious cases without the slightest fear.

At the hands of a number of French scientists, lately, pet animals have been coming in for their share of blame in the conveyance of infectious diseases. Two very striking reports have been made to the Academy of Medicine within a month. Gilbert and Fournier reported a series of some fourteen cases of a peculiar contagious disease which was almost always fatal (only two patients survived), which they traced to parrots. The specific cause of the disease is a bacillus that was described by Nacard in 1893 as having been found in the bone-marrow of certain parrots dead from the disease. The bacillus was found in the lungs of patients after death, and was rapidly fatal to guinea-pigs and rabbits, producing characteristic lesions. The microbe resembles very closely the bacillus of typhoid fever, and was at first supposed to be identical with it. It gives even the agglutinative reaction with typhoid serum, that has been considered so characteristic of Eberth's bacillus. Widal has pointed out within the past week, however, that there are certain distinguishing characteristics in the quality of its agglutinative action. The symptoms of the disease are those of a fulminant type of broncho-pneumonia, with intense depression, and Gilbert and Fournier are of the opinion that some of the reported family epidemics of pneumonia have been really due to this disease, for which they suggest the name, Psittacosis (πσιτταϰος, a parrot).

The dog has usually been considered very immune, or at least resistent, to tuberculosis. At one time injections of canine serum were suggested, I believe even employed, as a therapeutic measure in this disease. Dr. Cadiot now reports to the Academy of Medicine that in 205 autopsies on dogs, he found tubercular lesions 105 times. Only about half of the lesions were localized in the lungs. The dog is especially liable to mucous and cutaneous tubercular lesions. The nasal secretion often contains the bacilli, and the animals are peculiarly prone to have small and not easily noticeable but persistently discharging tuberculous fistulæ in the cervical region. The danger of infection, especially of children, is easily understood in such a case, and some of the cases of tubercular meningitis, where the family history and the personal environment give no trace of the mode of injection, may have had such an origin as this. The cat is reported by the same observer to have a series of mucous and cutaneous lesions very like those observed in the dog. The striking picture of the English observer in Iceland describing the children as "exchanging caresses and echinacocci" with dogs, is vividly recalled by the possibilities suggested by these observations.

Speaking of animals, one has been inclined to think that it is only in America that physiologic and bacteriologic work is hindered by the antivivisectionists, but, alas! it is now commencing in France, also. One of the recent numbers of Larousse's *Encyclopedic Journal* was devoted entirely to women and women's work, "*Les femmes et les feministes,*" and a leading paper bore the title: "Women and the Crusade Against Prostitution, Vivisection, Alcoholism, and War." Verily, the experimenters have gotten into unsavory company. The wonderful results achieved during the last ten years by experimentation on animals does not hinder the propagation even here of rabid fanatical ideas of ultra-carefulness of animal feelings. Even Magnan's now classical description of the antivivisectionists as a special class of degenerates coming under the same general head as a number of other monomaniacs—people who have a little too much of one quality to be perfectly sane—does not seem to have stopped the propagandism very much. Meantime, the medical profession in general, as with us in America, looks idly on. One would not think their interests were at all involved in the question.

OUR PHILADELPHIA LETTER.

[From our Special Correspondent.]

PHILADELPHIA HOSPITAL TRAINING SCHOOL FOR NURSES—COURTESY EXTENDED BY THE PHILADELPHIA POLYCLINIC—UNSANITARY CONDITION OF BAKESHOPS—BEER BOTTLES AS RECEPTACLES FOR SPECIMENS OF URINE.

PHILADELPHIA, January 2, 1897.

At the graduating exercises of the Philadelphia Hospital Training School for Nurses, held in the amphitheater of the hospital on the 29th of December, twenty-one nurses were awarded diplomas. Addresses were made by Dr. John H. Musser of Philadelphia, and Dr. William Osler of Baltimore.

No better illustration of the good feeling which exists between the medical profession of New York and Philadelphia, and especially between the teaching faculties of the two cities, could be had than the fact that upon the receipt of the news of the damage by fire on Christmas morning to the New York Polyclinic building, the Faculty of the Philadelphia Polyclinic promptly extended its sympathy and the courtesy of recognizing, without charge, the tickets held by the students for their unexpired term. This was gratefully appreciated by the Faculty of the former institution, but their prompt and vigorous action in providing facilities for continuing their work rendered acceptance of the courtesy unnecessary.

At the meeting of the Woman's Health Protective Association, held at Association Hall on December 29th, Dr. Benjamin Lee, Secretary of the State Board of Health, addressed the members on the subject of the unsanitary condition of the bakeshops of the city. He was present at the meeting in response to a request that he give his opinion on this subject. In the course of his remarks he said: The importance of removing the evils attendant upon the present filthy condition of the bakeshops is as great, or greater, than the importance of providing pure and wholesome milk. It is a matter of notoriety that in the outbreaks of cholera in Europe the workers in the bakeshops have been the first to be attacked by the disease, and it is also known that the mortality of bakers is greater than that of the average of artisans. These unfortunate results are due to the vitiated atmosphere of the cellars where baking is usually carried on. If the agitation for an improvement of the sanitary conditions were conducted solely for the welfare of the workmen in these shops it would be worthy of encouragement, but the need for it is very much greater in consequence of the spread of disease that must accompany the preparation of bread in such places. It has been suggested that a bill be introduced into the Legislature providing that the factory inspectors be instructed to inspect the bakeshops and enforce regulations as to their condition, but it would be more appropriate that the matter be under the care of the Board of Health.

A typewritten letter from the Pennsylvania Bottlers' Protective Association has been received by the physicians of this city, calling attention to an enclosed letter from a physician, deprecating the use of beer or other bottles originally intended for beverages, as receptacles for specimens of urine, and requests the absolute refusal of specimens brought in such bottles. The practice, though strenuously to be condemned, is unfortunately only too common in certain portions of the city, and especially in dispensary practice.

SPONTANEOUS DISAPPEARANCE OF SECONDARY CANCER.—ARSENIC CAUSES DISAPPEARANCE OF SARCOMA OF THE TESTICLE.—THE CAUSE OF PAIN IN MOVABLE KIDNEY.—SUCCESSFUL REMOVAL OF A GLIOMA OF THE CEREBELLUM.—TREATMENT OF PERITONITIS DUE TO PERFORATIVE APPENDICITIS.

AT a meeting of the Clinical Society of London, November 27th, PEARCE GOULD showed a case of *spontaneous disappearance of a secondary cancerous growth* in a woman aged forty-four years. Ten years previously she had received a blow on the left breast. Five years after this the breast was removed for scirrhous carcinoma. Recurrence of the growth was twice operated upon. The tumor again recurred, with difficulty in breathing, and it was considered inadvisable to perform any further operation, as the growth had probably become disseminated. There were numerous hard nodules around the scar, and considerable enlargement of the glands in the axilla and above the clavicle. She also had pain in the left thigh and one inch of shortening, and below the trochanter there was a large, bony growth. Nodules also appeared in the right axilla and above the right clavicle, and the right chest was dull below the spine of the scapula. This was the condition in March, 1896, when she was thought to be in the last stage of malignant disease, and her death was daily expected. Three months later she was much better. The enlargement of the axillary and clavicular glands had disappeared, dyspnea had ceased, and there was no dulness on percussion except at the base of the right chest. The nodules in the chest-wall had also disappeared, and the swelling of the leg had markedly diminished. There had been no treatment which might influence the progress of the disease. Microscopic examinations of the growths made by two competent observers revealed typical scirrhous cancer.

GOLDING-BIRD mentioned the case of a man, aged sixty, whose right testicle had been removed for sarcoma, of which he had microscopic sections. Three weeks later the stump fungated, and a large mass was removed, with as much of the cord as possible. In another three weeks there was an infiltration in all the surrounding skin. Morris saw this case, and unhesitatingly pronounced it malignant, but suggested arsenic in rapidly increasing doses. In ten days, when the poisonous dose had been reached, the growth had entirely disappeared. That was three years ago, and there has not been any recurrence.

At the meeting held December 11th, DAVID NEWMAN read a paper on *increased vascular tension in the kidney as a cause of renal pain, hematuria, and albuminuria,* in which he pointed out that the causes of increased vascular tension were (1) mechanical and (2) some morbid process. Thus a movable and large kidney in one of his patients caused severe paroxysms of pain, hematuria, etc., the symptoms resembling those of renal colic. There was no albuminuria, independent of the presence of blood. Suture of the kidney to the parieties relieved these symptoms. In another case of floating kidney, it was found that the rotation of the organ had coiled the ureter and blood-vessels around one another.

Another case was cited to prove that inflammatory hyperemia causing pain and albuminuria may be relieved by incision. This patient gave a history of lumbar pain, with small oxalate calculi, and occasional hematuria. The urine contained albumin, but no casts. While under observation, he had several attacks of renal colic. The kidney was found to be much enlarged, very tense and of a dark chocolate color. No calculi were found, and the bleeding from an incision into the pelvis of the kidney was so free that the wound in the cortex had to be plugged with iodoform gauze. The patient made a good recovery, the albuminuria entirely disappeared, and his health has since been excellent. Two other cases were mentioned, in which strangulation of omentum or bowel was accompanied by renal hyperemia, with almost complete suppression of urine, which the author thought due to a reflex spasm of the renal vessels of the ureter.

BRUCE CLARKE thought that obscure symptoms of calculus were often due to movable kidney.

BARKER, referring to those cases of supposed calculus in which none was found on operation, but in which all symptoms thereupon subsided, suggested that minute disseminations of uric acid in the tubules were dislodged by manipulation. An unsuccessful exploration for calculus is often followed by large quantities of uric acid in the urine.

PARKIN had removed from a four-year-old child in June, 1894, a *gliomatous tumor of the cerebellum*. For several months there had been gradually increasing difficulty in walking and talking. The gait was ataxic, with a tendency to fall backward. The left leg was rigid, and both knee jerks were exaggerated. The temperature was subnormal, pulse irregular, but not slow. There was no occular paralysis, but intense optic neuritis with hemorrhages. The child was listless, complained of constant headache, and had three severe general convulsions. Her condition was rapidly becoming worse. A large scalp flap with the apex well down on the neck was raised upward, the bone was removed, and a flap of dura mater, with the apex upward, was turned downward. The occipital sinus was ligated. A portion of each lateral lobe, and the posterior part of the middle lobe, were of a different color from the rest of the cerebellum and were excised. In three months the child recovered the power of walking and talking, and up to the present time (2½ years) there has been no return of any of the symptoms. Examination of the tumor showed it to be a glioma.

Another interesting case of brain surgery was described by GUTHRIE at a meeting of the Royal Medical and Chirurgical Society, held December 8th. The patient, a man aged twenty-five, had suffered for twenty-two years from violent jactitations of the left arm and leg, and in a less degree of the right arm and leg. The movements were ataxic, choreaic, and clonic in character, and were increased by attempted voluntary action. There was external strabismus and proptosis of the left eyeball. The tongue deviated to the right. The symptoms seemed to indicate functional perversion of the right motor area of the cortex. On operation, this area was healthy in appearance, but electrical stimulation of the thumb centers produced fits of Jacksonian epilepsy. The thumb center with the adjoining area of the cortex, measuring about one-half inch in diameter, were excised. The result of the operation was complete paralysis of the left hand and arm, lasting about a week. During this time he had seventeen epileptic fits, at first affecting the right side only, but afterward becoming universal. After a week, voluntary actions of the left arm were recovered, but they became increasingly jerky and ataxic until, in three months, his condition was the same as when the operation was performed. It was concluded that the excision of cortical centers is only likely to arrest movements permanently when they are extremely limited in range and extent, and in such cases the operation is unnecessary. In severe cases the removal of cortical areas might possibly arrest the movements permanently, but the dangers of operation overbalance its possible advantages.

At a meeting of the Medical Society of London, held December 14th, MAYO ROBSON described six cases of general peritonitis following perforating appendicitis on which he had operated during the past year, and five of which had recovered. His treatment was very free irrigation with water or weak boracic acid solution, followed by free drainage with several large rubber tubes.

Berlin.

GASTROENTEROSTOMY FOR CARCINOMA.—ACTINOMYCOSIS OF THE JAW.—LEPROSY.—ESOPHAGOTOMY FOR THE REMOVAL OF FALSE TEETH.—THE WARM BATH AS AN AID TO ABDOMINAL PALPATION.—HEMORRHAGE FROM THE HEALTHY KIDNEY.

In the Medical Society, November 4th, ROSENHEIM presented a patient upon whom had been performed *gastroenterostomy for carcinoma* of the stomach two and a half years before. At the time of the operation the general condition of the patient was bad, and the tumor was so extensive that a radical removal was out of the question. Although the tumor had continued to grow, the general condition of the patient had improved and she was still very comfortable. In such cases this operation should be recommended, because it frees the patients from the constant, fearful pain and uncontrollable vomiting from which they suffer.

GLUCK presented a patient who had suffered from *actinomycosis of the jaw, parotid gland, and the associated soft parts*, requiring the removal of the right half of the right jaw and the parotid, and the ligature of the external carotid artery. The wound healed perfectly, but no apparatus had been successful in enabling him to chew solid food. Gluck also exhibited skiagraphs of a boy, a portion of whose jaw was removed nearly three years ago for myxofibrosarcoma. The sections of the jaw were held in position by a strip of metal screwed into the bone. The result was perfect, and the action of the lower jaw was normal. Such substitution of ivory or metal can only succeed in case of healthy ends of bone which are capable of regeneration, absolutely aseptic union, and perfect fixation. Faulty asepsis leads to suppuration, erosion of the bone, and ulceration. Imperfect fixation produces an osteitis and a gradual loosening of the ivory, bone or metal.

Havelburg discussed the subject of *leprosy*, more especially with reference to its occurrence in Brazil, where he had had large experience. As yet no attempt to cultivate the leprosy bacillus has succeeded, nor have any inoculation experiments upon animals. He believed in the contagious character of the disease, although unable to say in what way infection occurs. Apparently unfavorable hygienic conditions are required before the bacillus can obtain a foothold. At any rate, the great majority of cases occur among persons living in the most filthy condition. The period of incubation is doubtless a long one. For example, a man and a woman who had lived in good circumstances in Brazil for a long period returned to Germany, apparently in perfect health. The man, after a year and a half, and the woman, after two years, developed the disease.

Koebner asserted that there was no reason for the alarm felt by the public if a single case of leprosy was discovered in some hotel; that the disease could not be communicated by brief contact with the person affected, but that only those individuals contract leprosy who have an intimate association with lepers for months or perhaps even for years. In cases of difficult diagnosis, the method recommended by Kalindero is of service. He discovered that in the contents of a blister the bacilli appear within three or four days. The repeated examination of the blood is also essential. The history of various cases had convinced him that extraordinary and unknown circumstances were necessary to explain the contagion of leprosy.

Joseph narrated an instance in which a child of healthy parents which had a leprous wet-nurse afterward became leprous. He was of the opinion that one distinct case of this nature outweighed a great deal of negative testimony regarding the contagion of the disease. The method of contagion is truly unknown, but more examination ought to be given to the sputum, which often contains leprous bacilli in great numbers.

Franz Koch looked upon leprosy as contagious and incurable, and advocated the complete isolation of lepers.

Rosenheim exhibited, at the session of November 11th, a *patient who swallowed a plate with four false teeth*. On the following day, a sound was arrested at a distance of 24 cm. from the gums. On the next day a 12 mm. sound passed readily into the stomach. It was therefore thought that the teeth had passed out of the esophagus. They did not appear in the stools, and after four days, by means of an esophagoscope, the false teeth were plainly seen, just below the larynx. All attempts at extraction failed, and so firmly were they fixed in the esophagus that after an incision had been made it was necessary to cut the plate in pieces in order to remove it.

The wound suppurated, and on the fourth day after operation the patient completely lost his voice, on account of paralysis of both laryngeal nerves. As this symptom did not arise until four days after operation, it was attributed to an inflammation in the nerves, proceeding from the suppurative peri-esophagitis. Aside from this point, the case was interesting in showing the failure of a sound to detect the foreign body, whose presence was easily made out by the esophagoscope.

In another case—that of a girl who in sport had swallowed three 10-mark gold pieces, eight days passed before an examination was made. Here again with the esophagoscope the coins were plainly seen and were easily extracted, although 34 cm. from the teeth.

The advantage of *abdominal palpation in a warm bath* was brought forward by Lennhoff. The influence of the warm bath relaxes the skin, as well as the voluntary muscles. After a patient has been for ten or fifteen minutes in a bath as warm as can comfortably be borne, abdominal palpation can be carried out almost as perfectly as in narcosis. This method possesses also the advantage that voluntary respiratory efforts can be called upon for assistance is diagnosis. Its absolute freedom from danger is another point of superiority. Lennhoff mentioned two cases in which by this means he had been able to confirm a suspected diagnosis. In one instance he made out a carcinoma of the stomach about the size of a hazelnut. It could not be felt at all by the usual methods of examination. In another case he settled the diagnosis, which lay between a carcinoma of the stomach and an aneurism of the aorta, in favor of the former affection. Both of these diagnoses were confirmed by autopsy. For convenience in examination, the patient is suspended in the tub by straps, which can be raised or lowered at will.

At a session of the Union for Internal Medicine, held November 16, 1896, Litten presented a case of *peculiar configuration of veins of the thorax and abdomen*. There were six parallel dilated and tortuous veins extending from Poupart's ligament to the sternum and ribs. Examination of the chest showed a tumor on the right side. This proved to be an aneurism of the ascending aorta, which so compressed the right ventricle that the vena cava inferior was obstructed. Owing to the fact that this obstruction was gradual, collateral circulation through the azygos veins was established and immediate death was avoided.

At the session of November 30, 1896, Klemperer spoke of the occurrence of *hemorrhage from the healthy kidney*. This occurs in cases of vicarious menstruation. Psychical influences may also cause vaso-dilation and bleeding. Hysterical hemorrhages are to be included under nervous influences. The author had known two such cases. There are in medical literature a number of cases of bleeding from the kidney supposed to be due to a calculus. In some of these the kidney was removed, and in others merely incised. In none of them was anything found, but the operation was followed by recovery from the bleeding.

Klemperer divided the cases into: (1) acute, due to over exertion, such as mountain climbing; (2) chronic, which may be either hemophylic or angioneurotic in character. Only a single hemophylic case had been reported. The author mentioned two others. The hemorrhages occurred at irregular intervals with more or less pain. The presence of blood cylinders in the urine proved the hemorrhage to be of renal origin. Both cases recovered without operation, one of them after the use of warm baths associated with cold local douches. Two cases of renal hemorrhage of the angioneurotic type were confirmed by cystoscopic examination. Both recovered, one after the removal of the kidney, which was found to be absolutely normal. In hemophylic or neurosthenic persons, although the hemorrhages may have continued for a long time, if no organic trouble can be made out, operation is distinctly contraindicated.

Nitze spoke in favor of simple incision to expose the kidney in doubtful cases—a harmless procedure which sometimes gives most valuable information.

SOCIETY PROCEEDINGS.

NEW YORK ACADEMY OF MEDICINE—SECTION ON GENERAL MEDICINE.

Stated Meeting November 17, 1896.

Reynold W. Wilcox, M.D., in the Chair.

Andrew H. Smith, M.D., read a paper entitled

ANEMIA IN RELATION TO CARDIAC DISEASE.

He commenced by saying that when it is remembered that the three prominent characteristic signs of organic disease of the heart, namely, dyspnea, edema of the lower extremities, and the presence of a cardiac murmur, are also found in connection with and as a result of anemia, it can be readily appreciated that when both of these conditions are conjoined in the same individual a good deal of nice discrimination is required in order to assign to each factor its proper share in the causation of the phenomena met with. Unfortunately, he said, the tendency is to ignore, in a great measure, the functional disturbances, and deal only with the effects of the organic lesion or lesions present; so that proper consideration is not given to the importance of the blood changes taking place, which, unless interfered with, will eventually produce the most disastrous results. This is a grave mistake. It should always be borne in mind that in organic disease of the heart nature provides compensation by means of hypertrophy, and that the patient is in no danger from this source as long as the compensation remains adequate. Our efforts to sustain the heart directly should, therefore, be reserved until the time when this compensating power of nature begins to fail. In the meanwhile our attention should be mainly devoted to improving the condition of the blood; by which means material assistance can be rendered the patient. By eliminating the anemic element, the whole system can be invigorated and the heart thus enabled to stand much better the strain resulting from the organic trouble present.

As a matter of fact it has been found that in a large proportion of cases, anemia is present in connection with the organic disease. This is not to be wondered at when we reflect that the most prolific source of such organic trouble is rheumatism. Not only does the rheumatic disease itself impoverish the blood, but, unless special pains are taken to prevent this result, the salicylic acid and its compounds so commonly given in rheumatism have the effect of increasing this impoverishment. To a patient suffering from organic lesions of the heart, therefore, anemia is a matter of importance, and coming on or continuing when the compensation becomes defective, it is of grave import. The vigor of the constitution is seriously impaired and a vicious circle is established. Unless the progress can be arrested the course of the case will be rapidly downward.

The most obvious symptom of anemia is pallor, but in these cases this is liable to be obscured by cyanosis. Stephen Mackenzie has suggested, however, that an approximate idea of the extent of the anemia present can be obtained by an examination of the nail tips. As long as any pink hue remains here it may be inferred that the blood contains at least fifty per cent. of the normal quantity of red corpuscles. Fortunately for the matter of diagnosis, anemic murmurs are confined to the systole. A soft systolic murmur, of low pitch, heard in the pulmonary area, is that commonly met with. In the aortic area the vast preponderance of bruits are of organic origin. Hemic murmurs also occur very rarely in the mitral region. When they do occur there we do not find the displaced apex and forcible impulse met with in organic mitral disease. Leaving the cardiac region, we find anemic murmurs also in the arteries of the chest and neck. In pronounced anemia a murmur is heard with each ventricular systole. An arterial murmur might be met with where there is no bruit in the pulmonary area, and *vice versa*. A venous hum in the great veins of the neck has long been recognized as a prominent sign of anemia; but this venous hum is not entirely characteristic, since it may in some instances be heard when the individual is perfectly healthy. Still, its presence will often enable us to decide that a co-existent cardiac murmur is not of organic origin.

As to the dyspnea, there are no means at our command of distinguishing that due to anemia from that due to organic disease. Edema of the lower extremities, as had been mentioned, is common to both conditions; but if to this is added a more general puffiness over the body, it might be assumed that considerable impoverishment of the blood is present. The most conclusive evidence of the existence of anemia, however, can be obtained by the direct determination, by means of the instruments now at our disposal, of the proportion of red corpuscles and hemoglobin in the blood. Dr. Smith urged the importance of very frequent examinations of the blood, so that if it is found that one remedy is not satisfactorily combating the anemia, another may be substituted.

The treatment of the anemia met with in connection with organic cardiac disease is not essentially different from that of anemia in other conditions. The necessity for relief of the blood condition is so urgent, however, that the most prompt and efficient measures are called for. In his own experience nothing had proved so satisfactory for the purpose required as the use of enemata of defibrinated bullock's blood. Of course, this did not exclude the use, by the mouth, of such other remedies as seemed indicated. The point that he wished to emphasize was, that, not only in advanced, but in the early stages of cardiac disease, the evidences of anemia should be sought for, and he was convinced that if the importance of this was recognized, we could avert many dangers, and carry our patients along in a much more satisfactory manner than otherwise.

Dr. Beverley Robinson said that while there were many cases in which the differential diagnosis was perfectly simple, all clinicians met with some in which they had a great deal of difficulty in determining just what belonged to the one condition, and what to the other. In this class of cases he believed it was often a good thing to look up the older authorities, like Stokes, for instance, who treated such subjects a good deal more fully than more recent authors, such as Flint, Loomis, and Osler. We were not, he thought, always making progress, simply because we changed our methods. An advance, however, had certainly been made in the present plan of examination of the blood. Still, when it came to the very difficult cases, even this procedure did not clear up some of the doubtful points.

We are, therefore, brought back to the question of systolic bruit at the apex. We feel that it is not entirely due to anemia. There may be dilatation of the left ventricle, and it is important to make out what part belonged to the anemia and what to the organic cardiac disease. All that he could say was that in reasonable doubt the physician should be judicious and sensible in the course pursued. A certain amount of heart tonics, such as digitalis, strophanthus or nitroglycerin, with moderate doses of strychnin, may be called for on account of the heart's action. When this blowing murmur is present it is not the part of wisdom to give large doses of digitalis or strophanthus. The great indication, as Dr. Smith has pointed out, is to improve the condition of the blood.

When the anemic condition is present no one could doubt for a moment that it adds very greatly to the gravity of the cardiac disease. We know that it will take both time and the most judicious management to get rid of it, whether it be secondary or primary. Of the remedies recommended, iron and manganese are the ones most commonly resorted to. He did not believe it very important that we should use this preparation or that preparation. Almost every physician has come to feel special confidence in some particular form of iron, and if he gets good results from it, it is better to stick to it than to go on trying every new preparation that the druggists throw on the market. At the present time it is the fashion to maintain that the organic salts are a great deal better than the inorganic ones, but, for his part, he had not yet seen sufficient evidence to convince him of this fact. His experience had taught him, however, that there are quite a number of cases in which iron may be given indefinitely without producing any result whatever, unless at the same time oxygen is administered artificially. He believed that the oxygen has the effect of rendering the iron more assimilable, but whether this is the case or not, he knew it to be true that the two combined successfully overcome anemia in some cases where iron alone has no effect. In conclusion, Dr. Robinson spoke of the efficacy in anemia of sulphur baths, either artificial or natural. He had been at Aix-les-Bains during the past summer, and he said that while much of the benefit which invalids received there was no doubt due to the change of air and life, he was convinced that the principal good effect in anemic cases was due to the sulphur baths. He believed that the same good results could be obtained by artificial sulphur baths at home, and especially in the case of young girls with slight degrees of anemia. Care should be observed, however, that the baths were not too warm or too long.

Dr. William H. Thomson said that he felt somewhat disappointed that the reader of the paper had confined himself almost exclusively to the consideration of the hemic murmur. He thought the functional murmurs among the most important that we meet with. He had known of more than one individual to be rejected by life insurance examiners on account of a harsh, regurgitant murmur which was purely functional, and with no anemia present. There are also very strange murmurs incident to the act of respiration. These are all systolic, and certainly functional. A diastolic aortic murmur and a presystolic murmur cannot be functional. Having spoken of the murmurs heard in chlorosis, he referred to a class of functional murmurs which are met with in nervous individuals, as often in men as in women.

He related a case of this kind. A gentleman came to him trembling with excitement about his heart. He complained of pain in the precordial region, and an examination revealed the presence of a booming and buzzing murmur at the apex, which presented some of the characteristics of a mitral regurgitant bruit. The patient, having been asked to lie down, it was found that in the recumbent posture the murmur was very much diminished. When the pulse had declined from 100 to 80 it was found that the murmur had almost entirely disappeared. He was requested to take a long breath, and it was then found that it was gone altogether. It certainly would not have disappeared if it had been due to organic changes at the mitral valve. The recumbent position does not make an organic mitral murmur disappear, especially if the patient lies on the left side. The quality of the sound was also different from that heard in connection with a mitral regurgitant murmur, being, as had been said, booming and buzzing in character. Furthermore, it did not transmit to the left, and the greatest intensity was not at the apex, but in the fourth interspace, to the right of and above the apex. This kind of murmur he believed to be due to the irregular action of an excited heart, and was of muscular origin.

Another kind of functional murmur is that heard during certain acts of respiration, particularly inspiration.

One peculiarity of it is, that it is heard on both the right side and the left side, but away from the area of the heart (in the axillary region.) It is evidently produced in the lung, though he had no theory to advance as to the manner of its production. He could only say that it is to be found at a distance from the area of the heart, and that it unquestionably is a functional murmur.

Anemia, he went on to say, is in his opinion often the direct cause of cardiac disease. Throughout the animal kingdom the muscular power is proportionate to the amount of respiration. Among our women this does not seem to be the case, but the female peasants of Europe, and the women of the East, who are accustomed to work out of doors, are capable of enormous physical exertion. It is a fact that needs no demonstration, that the very first effect of anemia is to produce muscular weakness all over the body. The blood flowing from a muscle when it rested was more venous in character than the blood in the right side of the heart. Therefore, anemia always meant muscular weakness, and if it persisted it inevitably produces degeneration. There is no condition of fatty degeneration of the heart so pronounced as that met with in pernicious anemia. It is a mistaken idea to give iron simply because there is anemia. If there is any elevation of the temperature it does harm. Especially is this the case in acute articular rheumatism. So also in phthisis. In the anemia of both these affections cod-liver oil is much better than iron.

DR. FRANK W. JACKSON said that although Dr. Smith had claimed that anemic murmurs are always systolic, he thought that everyone who had had much experience in this class of cases must have found exceptions to this. Occasionally an anemic murmur might be diastolic, and various authorities had confirmed this view. He had himself, in several instances, heard a presystolic murmur in patients who were suffering from anemia and who afterward returned to health; showing the absence of organic lesions. As to dropsy of the lower extremities, Dr. Smith had maintained that it is apt to be more diffuse in anemia than in organic cardiac disease; but he did not think this distinction was of much practical service, as he was sure that everyone had met with anemic cases in which it was just as diffuse as in the latter. As to anemic murmurs being intensified by the recumbent position, he had found many cases in which the change of position produced no change whatever.

DR. H. NEWTON HEINEMAN said he thought it was about time that the profession should get rid of the idea that in any case that is at all difficult the diagnosis could be made upon a few data. Whether anemia is present or not, it is requisite that the physician should be in possession of a knowledge of the complete clinical history of the case, the exact character of the murmurs present, and the amount of arterial tension. If these and similar points were more carefully studied, there would be much less doubt in the minds of medical men than is at present the case. It is well to bear in mind also that the intensity of the murmur in any case bears no relation to the gravity of the lesion. Dr. Heineman spoke for some time in regard to the efficacy of baths. In all cases where it is possible, he thought that the patient should be sent to the location of the natural springs. While the sulphur baths of Aix-les-Bains were of great value in gout and rheumatism, he thought they were of no service in cardiac affections. The saline baths of Bad Nauheim, on the other hand, he believed were highly advantageous in diseases of the heart and circulatory system, promoting rapid tissue-metamorphosis. The chalybeate waters of Pyrmont were of special value in chlorosis. In many instances, however, artificial saline baths could be used with great advantage at home.

DR. SMITH, in closing the discussion, said that regarding the muscular murmur spoken of by Dr. Thomson, all the evidences of anemia were wanting. It was the sound, he thought, described by the late Dr. Austin Flint as intraventricular, and was a local muscular effect. As to the sound apparently referable to the respiratory act, he did not believe it was very common. He had met with it in three instances. One of them was a young girl, in whom it was sometimes present and sometimes not. It was a moderately harsh murmur, and occurred in inspiration, but not in expiration. He said he agreed with Dr. Thomson in regard to the harmfulness of iron in febrile conditions. In regard to the matter of diastolic murmurs, supposed to be of anemic origin, spoken of by Dr. Jackson, he said that this brought us back to the question of the possibility of such a thing as a presystolic murmur. Personally, he was not willing to accept its existence, and believed that the so-called presystolic murmurs were not really presystolic, but were heard just at the beginning of the systole.

H. NEWTON HEINEMAN, M. D., read a paper entitled

STENOCARDIA (ANGINA PECTORIS).

(See page 37.)

DISCUSSION.

DR. FRANK W. JACKSON said that the distinction referred to in the paper had always been somewhat a matter of wonder to him. If the pain were not very severe, the case was called one of pseudo angina; if it were severe, one of genuine angina. He thought stenocardia, also, a much better term than angina pectoris. The treatment advocated by Dr. Heineman, he went on to say, offered us new hope for our patients. He had always been afraid to tell an individual that he suffered from angina pectoris, as such a statement was commonly regarded by the public as equivalent to a death-warrant. It would be a great gain to be able to tell his patient now that he had heart-pain, and to encourage him to look forward to recovery. Still, it seemed to him that we cannot exclude pseudo angina altogether. We must recognize the fact, he thought, that we can have cardiac pain present, and yet not a true angina.

DR. CHARLES E. QUIMBY thought that the pseudo anginas might be regarded as a temporary anemia. The effect, which he believed was the important factor in the treatment by saline baths, was the relief of the capillary circulation. He then went on to speak of the modifying effect upon the heart of varying degrees of atmospheric pressure.

THE MODERN ASPECT OF TUBERCULOSIS.[1]

BY H. ARROWSMITH, M.D.,
OF BROOKLYN, N. Y.;
LARYNGOLOGIST TO THE HEBREW ORPHAN ASYLUM; LATE ATTENDING PHYSICIAN TO THE BROOKLYN HOME FOR CONSUMPTIVES.

IT is a reasonable assumption that, at this period, Koch's bacillus has a definite status, in general acceptation, as *the* factor in the direct etiology of all tuberculous diseases. It has satisfied every condition of proof that can be demanded, in that it conforms to the requirements of the formulated proposition to demonstrate that a given disease is caused by a specific organism: (1) It is present in all cases of the disease, and in such distribution as will explain the lesions. (2) It can be isolated in pure culture. (3) The disease is reproduced by inoculation with the isolated organisms.[1]

It may not be an entirely unprofitable task to review (though necessarily very briefly and superficially) the changes in the aspects of tuberculosis which have followed as direct results of Koch's discovery, and perhaps to indulge in a little speculation as to future prospects. We are still apparently a considerable distance from our goal—the ability to prevent the propagation of tuberculous disease and the means of treating it successfully when it occurs; but unquestionably a very distinct advance in our understanding and methods has been made. The investigations, of which the identification of the bacillus was the starting point, have at least demonstrated the fallaciousness of many older views and methods, and have given, if not definite results, at least most valuable indications of hygienic, therapeutic, and clinical possibilities which will, beyond doubt, work radical changes in the destinies of humanity.

There has been a great deal of diversity of opinion as to the exact rôle of heredity in relation to tuberculosis. Much importance has always attached to the transmission from parent to offspring of predisposition to tuberculous disease. To quote Billings,[2] "In most of the so-called hereditary diseases, that which is transmitted from parent to child is not the disease itself, nor its direct specific cause, but some peculiarity of tissues or organs which, in the course of development, either makes the person peculiarly susceptible to causes of disease acting from without or produces disorder itself by excess or defect of structure or function of some particular part. In scrofula, and in consumption and other forms of tuberculosis, the specific germ is very rarely, if ever, transmitted, inheritance giving only a special susceptibility to its action." Recent investigation seems to indicate that this view will be modified by further research, for tubercle bacilli have been found in seminal fluid by several observers,[3] [4] [5] and tuberculosis produced by inoculation of cultures made therefrom. The possibility of direct paternal transmission is slight, however, having been estimated at one chance in 22½ millions by one observer, taking into consideration the fact that impregnation usually takes place through the agency of one spermatozoid.[6]

Armanni succeeded in infecting a guinea-pig with typical tuberculosis by inoculation with the organs of a still-born child of a tuberculous mother.[7] Lehmann[8] reports the case of an infant of a tuberculous mother dying four days after birth with tubercles containing bacilli in the spleen, lungs, and liver. Tuberculosis of the placenta has been studied and described by Schmorl and Kockel.[9] In three cases observed, bacilli were found in the placenta, but in only one of them in the organs of the fetus. Bar and Rénon[10] demonstrated bacilli in the blood of the umbilical veins of children born of tuberculous mothers. Northrup reports a probable case of congenital tuberculosis examined *post-mortem* by him at the New York Foundling Asylum. General disseminated tuberculosis was found, and apparently the oldest mass was at the porta of the liver.[11] [12] Congenital tuberculosis in cattle has been observed not infrequently. What has been rather indefinitely known as scrofulosis is practically conceded to be tuberculosis, and that this condition is frequently congenital almost everyone will admit. A very interesting monograph, by Suchanneck of Zürich, which has appeared recently,[13] brings the subject of scrofulosis, in its relation to disease of the respiratory system, up to date; and he makes no distinction between it and tuberculosis.

The acquisition of tuberculous disease may take place through the integument by immediate inoculation of the poison on an abraded surface. Such processes are generally local, and instances are more or less familiar to us all of lesions which have occurred in our own persons, or in others who are exposed to frequent contact with infected material in the line of pathological or clinical work. Collins and Murray report three instances of infection by tatooing.[14] By some French authorities the ordinary bedbug is alleged to be an active agent in the transmission of tuberculosis. General infection is sometimes produced in this way, however, for Lehmann[15] speaks of ten boys who were circumcised by a tuberculous operator (who died from the disease shortly afterward). The wounds were infected by his saliva, and general tuberculosis and death supervened in seven instances, and three of the boys were living with tuberculous adenitis at the time of his report.

---

[1] Read before the Kings County Medical Association, October 13, 1896.

Tuberculosis of the cervical glands has been caused by infection through the means of carious teeth. The disease has been also directly transmitted by the act of coition. Infection by the way of the alimentary tract has been held by some writers to be the most usual of all the possible ways. It occurs from the ingestion of intrinsically diseased milk or meat, or of food which, though originally pure, has become accidentally contaminated by the bacilli. The results of investigations as to the existence of tuberculous disease in cattle furnishing our ordinary milk-supply, as well as the frequency of the lesions in those slaughtered for meat, are, to say the least, startling, and in this connection, if in no other way, Koch's tuberculin has been of enormous utility in permitting the identification of diseased animals with practical certainty. The literature bearing on this special feature is so extensive already that in a paper of this kind it will be impossible to review it in even the most cursory manner. The entire subject of milk infection has been dealt with by Professor Ernst,[17] under the auspices of the Massachusetts Society for the Promotion of Agriculture. He found that bacilli are sometimes present in the milk of cows having no demonstrable lesion of the udder. This was determined by microscopic examination, as well as by inoculation experiments, and he also observed that feeding infected milk to animals caused tuberculous disease in a certain proportion of cases. Brush[13] alleges a direct and constant relationship between human tuberculosis and the use of dairy products as regular articles of diet. He shows in a way that is almost convincing that tuberculous disease is infinitely more common in communities where cattle are bred for dairy purposes than in those countries where their products are not used in this way, as, for instance, in Argentina, where, although there are in the neighborhood of twelve million head of cattle, no butter or cheese is produced, and where such a thing as a dairy farm is unknown. The indigenous population is practically immune. Roth of Zürich has found virulent tubercle bacilli in butter, in two out of twenty specimens examined.[19] What has been said of infected cows' milk is inferentially equally true of milk from diseased human beings, although I have no recollection of having seen any statements in regard to this point.

Occupying a position between the alimentary and respiratory systems as avenues of infection is the lymphoid tissue at the upper part of the two tracts. I refer to the tonsils—faucial, pharyngeal, and lingual. It has seemed to me that the facts which have been adduced as evidence of the part they play as starting-points of disease have been misunderstood, or magnified in importance. So-called "latent tuberculosis" of the tonsils was first described in detail by Dieulafoy.[20] He inoculated sixty-one animals with pieces of faucial tonsils, and tuberculous manifestations resulted in eight instances. Thirty-five inoculations with adenoid tissue gave positive results seven times. Lermoyez[19] reports two cases in which removal of lymphoid tissue from the pharynx seemed to give rise to generalized tubercular infection. In a later report he gave the proportion of tuberculosis to simple hypertrophy of the tonsils as one to seventeen; and in a third communication, as one to seventy-five. Schlenker, as a result of one hundred examinations, concludes that tonsillar tuberculosis is generally secondary to pulmonary disease.[22] Brindel of Bordeaux, after examining sixty-four adenoids, claimed to have found tuberculosis in eight, or 12½ per cent. of the cases.[23] Bacteriological investigation was practised in but one instance, and inoculation experiments in none, his diagnosis of tuberculosis resting on the histological discovery of occasional giant cells, which, it is needless to state, are found in inflammatory processes entirely distinct from tuberculosis, so that his results are practically valueless from a scientific standpoint. Chappell's case of general fatal tuberculosis developing after adenotomy,[24] is also assailable on the hypothesis, which from the clinical history seems very possible, that the tuberculosis of the pharyngeal growth was antedated by pulmonary disease. In this case, however, the diagnosis was certain; histological tubercle and bacilli were found and inoculations gave positive results. Several hundred adenotomies and tonsillotomies done during the past two years at the Brooklyn Eye and Ear Hospital have failed to reveal a single instance of tuberculous disease appreciable on *gross* examination. In a paper read this year before the American Laryngological Association, Wright[25] reports from his service at that institution examinations, microscopical, bacteriological, and by inoculation, which gave absolutely negative results in twelve consecutive unselected cases, and he reaches the perfectly logical conclusion that opposed findings have been due, in most instances, simply to surface contamination. This is further corroborated by the experiments of Strauss,[26] who in examining the nasal secretions of twenty-nine perfectly healthy individuals employed in a hospital where phthisical patients were treated, found virulent tubercle bacilli in nine cases.

The respiratory tract proper is probably the most frequent avenue of infection, and Hance's paper[22] on the "Infectiousness of Dust" gives a vivid picture of the ease and frequency with which the germs can be inhaled, and, on the other hand, the gratifying possibilties of simple means of disinfection and ordinary care. His investigations were carried out with great care and thoroughness at the Adirondack Sanitarium and certainly are an admirable object lesson to both the profession and the laity in the management of tuberculous patients. (See also Cornet.[62])

It is claimed by some observers that, irrespective of the channel by which the bacilli have gained entrance to the body, the lymphatic system is invariably affected before the lesions appear elsewhere. Northrup[11] found in a series of ninety-one autopsies made at the New York Foundling Asylum on children affected with tuberculosis, that the bronchial lymphatic glands exhibited signs of disease of apparently longer standing than any of the other organs. In thirteen of these cases the process was distinctly limited to them. Arnold[28] in experiments with reference to inhalations of dust by animals found that after a short inhalation the particles of dust might be identified in the bronchial glands. In inhalations of ultra-marine the particles were found after three hours, and after stopping the inhalations, though the bronchi and alveoli might be quite free of the particles, the glands were full of dust.

Aside from, perhaps, a better interpretation of the rational signs and subjective symptoms, comparatively little advance in the early diagnosis of tuberculosis has been made during the last fifteen years. Much has been written about the "pre-tubercular state"—"hypotrophy" antedating tuberculous processes, etc., but after extensive reading, and a not inconsiderable personal experience, I fail to find any distinctive particulars in which the prodromal stage of tuberculosis differs from that of any other chronic general disease before the characteristic changes have been made out. If certain physical signs can be definitely recognized, we are sure that we are right in our diagnosis, but their absence is by no means of equivalent value as indicating freedom from tuberculosis. Mensuration, as practised by Evans, may be a valuable aid in diagnosis. His method is very thorough, but rather too complicated and requires too much apparatus to be practically useful, except in the offices of specialists, or in institution work. (For full description of his Cyrtometer and Method of Application consult original article.[29])

The administration of tuberculin in the human subject, for diagnostic purposes, has been shown to be unjustifiably dangerous, and has been abandoned. The presence of the bacillus in the sputum, in such numbers and with sufficient constancy as to eliminate the factor of surface contamination above referred to, is of course pathognomonic, but at a time when this is likely to occur the expert diagnostician is usually able to decide on the evidence of the physical signs alone. Of course very many doubtful cases have been settled by bacteriological examination. It is, however, as true to-day as it was before Koch's discovery that we are in no position at any period before the evidences with which we have been long familiar can be made out, to say that our patient has or has not tuberculosis. A new line of investigation has been recently started which may lead to valuable results when its technic shall have been further elaborated and when sufficient experience shall justify reasonably definite deductions from the microscopical appearances. I refer to morphological changes in the blood occurring in tuberculosis. Holmes of Denver[30] has recently published an article on some original studies he has undertaken in this connection, and his paper has been supplemented by one from Denison.[31] Both papers are more interesting than practically valuable, but that in further and fuller observations in this line we may find a reliable means of early diagnosis seems, from what they say, not impossible.

As to prognosis, I think that it can be definitely stated that tuberculosis is at the present time an incurable disease. By this I mean that it is incurable as are also typhoid fever, smallpox, and many of the other specific diseases for which we have as yet found no direct antidote. Probably at least as many patients recover from tuberculous lesions as succumb to them; this is a matter of clinical and pathological experience. I question very seriously, however, whether any form of treatment which has yet been practised has directly modified the tubercular process in the slightest degree. These apparently paradoxical statements I shall try to explain later on.

There is generally present in tubercle a tendency to resolution, and spontaneous arrest of the process and involution of its products occur frequently, apparently entirely irrespective of any attempts at medication. There have been strides during the last decade, if not in treatment at least in prophylaxis, as applied to the community as well as to the individual, which have borne fruit of very distinct character. The appreciation of the methods of propagation has logically brought with it the suggestion of remedies adapted to their requirements. The first systematic attempt at sanitary supervision of tuberculosis was made in New York in 1893, and in spite of much opposition it has already had the result of appreciably decreasing the relative mortality from this disease. The few simple rules of disinfection and individual care necessary to limit the spread of tuberculosis are too generally understood to require elaboration. The circular published and distributed by the New York Board of Health has been of practical use in making clear to the lay mind the characteristics of tuberculous disease, and that the recommendations contained in it have had some effect is evidenced by the decrease in the death-rate from tuberculosis. That the mere suggestion of such simple measures, without any attempt to enforce compliance with them, has been followed by tangible results in so short a time is a most encouraging indication that a more extensive dissemination of knowledge, combined perhaps with a little more latitude and power in the exercise of the functions of sanitary boards, may in time inhibit the spread of tuberculosis to almost the same limit to which the propagation of smallpox is now confined. (For detailed information as to what has already been accomplished in this direction I refer, among a large number, to papers by Biggs and Huddleston,[32] and Hance,[27] and to the report of the meeting of the Section on Public Health of the New York Academy of Medicine, November, 1895.[33]) Radical measures in this direction are impracticable and unwise; results are more likely to be attained by work on educational lines than by direct legislation.

Sanitary supervision of the food supply can and should be conducted in a more vigorous way. The imperative need for strict supervision is shown by the fact that in one year of the cattle slaughtered in Berlin for food 21,000 were found to have tuberculosis. An inspection of the cattle in the kingdom of Saxony showed them to be affected in the proportion of one to seven of the oxen, and one to four of the cows.[34] Similar statistics might be quoted indefinitely, but all show the same facts and teach the same lesson—the enormous prevalence of tuberculous disease among the domestic animals, and the importance of the most energetic and systematic efforts to eradicate it. (See, also, E. F. Brush, "Consanguineous Breeding," etc.[35])

The principles underlying individual prophylaxis are too well appreciated to require more than a passing mention, though, unfortunately, they are rarely carried out as they should be. Proper nourishment, clothing, habits, fresh air, exercise, and the strengthening of weak places and the avoidance of the possibilities of infection, have been written on voluminously.

I shall not enter into a discussion of the treatment of tuberculosis as bearing on the general management, nor in relation to the special symptoms, except in passing. Climate has been always a much-discussed therapeutical resource in tuberculosis, and perhaps no one agent at our command has been so extensively abused, misunderstood and misused. The fact that certain cases of phthisis have improved at special health resorts has in many instances seemed to be a sufficient reason for referring to these localities *all* patients with consumption, entirely irrespective of the character of the disease, its stage, complications, or other features which might modify to a marked degree the effects of the special climatic conditions. The indiscriminate prescription of climatic change, without due regard to the exigencies of the individual case, has probably done more harm, shortened more lives, and destroyed more possible chances of recovery among consumptives, than ignorance or faulty application of any other remedy that has ever been employed in the treatment of phthisis. "One of the chief reasons of the climatic benefits of sea and mountain air is the absence of poisonous and irrirating substances floating in it."[36] That, I believe, contains the gist of the whole question of climato-therapeutics, other things being equal. To generalize, I believe that the ideal climate for the average consumptive is not at any special station nor at any given altitude, but where is found pure air free from contamination, in a reasonably equable, moderate climate, with good drainage, and where the percentage of moisture is approximately normal and not subject to great variation. To such a place there is no rational objection to sending *any* patient who is fit to leave home. I do not question that there have been many recoveries at high altitudes; but many patients have been irretrievably harmed by a residence in them. The contraindications for altitude are sufficiently definite to enable us to select, with fair judgment, the patients who can stand the conditions and who are likely to be benefited. The ideal resort, as I have outlined it above, is most likely to be found, in our country, at a moderate elevation—from 1500 to 2500 feet—and its name is legion. Many climatologists have written about an "Altitude of Immunity." Denison places it in Colorado at an elevation of approximately 6000 feet.[37] It may exist *somewhere*, but probably at a height which is immune from human as well as germ life. That this idea is rather chimerical is evidenced by the fact that one of the observers employed at the Signal Service Station on Pike's Peak, 14,000 feet above sea level, developed *there* a fatal pulmonary tuberculosis some years ago.

That it is a question more of an aseptic atmosphere, with reasonably favorable prevalent meteorological conditions, than one purely of altitude and rarefaction of the air, can be deduced from the progressive contamination of health resorts. To such an extent has this occurred that I understand that the State Board of Health of Colorado (where are located some of our most popular high-altitude stations) is seriously considering the advisability of placing an embargo on the immigration of any more tuberculous patients, as a matter of self-protection. And in this connection, I cannot help quoting verbatim the following in reference to a once widely known and popular health resort:

"Forty years ago, Mentone was a healthy village in France, where lived peasantry on their farms, happy in their superb physical state conditioned by the climate. It was discovered that the region was a most healing climate for consumptives, and it became the Mecca for the unfortunates of Europe so stricken. The strong, healthy women forsook their dairies and became the washerwomen of the consumptives' clothes. No precautions were taken; the disease was not understood then, as now. The place is to-day bacillus-ridden, a pest-hole—death itself. The hitherto strong inhabitants are emaciated, a coughing, bleeding people, filled with the germs of consumption. The soil and air are both contaminated with them. It is no longer a resort."[38]

J. A. Lindsay[39] tersely expressed the present aspect of the climatic treatment of phthisis in the following words: "Climatic change is a snare, rather than a help, a curse rather than a blessing, if it be regarded as a complete therapeusis in itself and as enabling the patient to dispense with the usual lines of treatment and his customary precautions. Climate is not a specific; at best it is only a condition of cure; and we may expect it to be effectual only when the patient's food, habits, occupation, and mode of life are wisely regulated so as to facilitate its beneficent influence."

In this relation, a word about ozone, of which we hear so much in connection with the beneficial attributes of health resorts. Very little is actually known about it. Most chemists regard it as allotropic oxygen, the molecule containing three atoms of oxygen. It is present in atmospheric air in the proportion of one part in 700,000. "The value of its presence would appear to be more an evidence of atmospheric purity than as a disinfectant, as it is absent when injurious decomposition is going on."[36] Thompson,[40] as a result of his experiments on the action of ozone and its compounds, reaches the conclusion that "ozone is of no value to the tissues, whether inhaled or drunk in fluid preparations, and it may be exceedingly harmful."

Preliminary to a consideration of the direct application of medicinal agents in the treatment of tuberculosis, it is well to realize exactly the conditions with which we have to deal. Here comes in a fact of the greatest possible importance, and a true understanding of it will doubtless furnish an explanation of some of the failures of the past, and indicate the chances of future success. We have been a little too prone to consider that tuberculosis consists merely of the presence in the organism of a specific bacillus and the formation of histological tubercle, and that the subsequent symptoms directly result from this combination. But these conditions do not, by any means, constitute the disease as we see it clinically. Tuberculosis rarely, if ever, runs its course as tuberculosis pure and simple. If it did, we could, perhaps, treat it with more success than we have hitherto attained. Some perversion of nutrition must exist before the bacillus can find a favorable soil for its development, and even then the process of the evolution of the disease, as evidenced by the increasing metabolic changes in the organism, the phthisis would probably be a very much more chronic and less serious matter, were it not for the complication of other bacterial infection. As a matter of common observation, patients rarely feel particularly debilitated, and are much more amenable to treatment before the stage of softening, and this is due to the fact that at this time the influence of other bacteria begins to be a factor in the disease, and becomes after a time the predominating element. Streptococci find in the diseased lung-tissue a fertile soil for multiplication and growth, and as a result we have superadded to the tuberculous process itself a continuously operating source of pyemic and septicemic phenomena which sap the patient's vitality and resisting powers and make him eventually a victim (though generally in an indirect way) to a poison which he might be able to withstand had it come singly.

Here we are tempted to ask ourselves what our present knowledge and the resources at our command warrant us in definitely expecting in the treatment of tuberculosis. As regards *direct*, *specific* influence on the bacillus, little or nothing (though we may modify this later on); as regards the patient, everything, even up to a condition of relative recovery. Up to the time of the discovery of the bacillus, the treatment of tuberculous disease by means of drugs was symptomatic and very largely empirical. Two of the remedies that were very widely employed in the general routine treatment are still considerably in evidence—the hypophosphites and cod-liver oil. Aside from their general tonic and alterative effects, the hypophosphites of lime and soda have been administered in the hope of promoting or producing calcification of tubercular areas. It is highly improbable that they ever assisted in this process to the slightest degree. Cod-liver oil has been administered as a matter of routine in larger quantities than any other remedy. My personal experience has led me to the opinion that it is *very much worse than useless.* The most that I have ever felt justified in hoping from it has been that it would *not do harm.* I have *never* seen it act beneficially. Patients who improve during its administration, do very much better, as a rule, after discontinuing its use. "It acts as an alterative, by changing decidedly the oxidation processes of the system. But, unfortunately, its alterative effects are in the wrong direction, decreasing the perfection of the proteid oxidation and often depriving unfortunate patients of the single chance of recovery which they might otherwise have retained. The free ingestion of it rapidly decreases the urea in the urine, and increases the incomplete or imperfect products of nitrogenous waste. The more perfectly it is emulsified, the more detrimental it becomes, because, thus, it is more palatable, and is less likely to produce digestive disturbance, and to be, therefore, refused entrance to the system. The emulsion also favors the absorption of an immoderate quantity, thus exhausting the oxygen supply and rendering the sub-oxidation of the proteid molecule, with all its ill-effects, doubly certain. It disturbs digestion and prevents the utilization of other and more valuable forms of food stuffs."[41]

Since the identification of the bacillus, every effort has tended toward the discovery of some agent (and a suitable means of applying it) which would directly destroy the germ and aid in its elimination from the organism, or, at least, inhibit its growth and neutralize its toxic influence. William Pepper was, I believe, the first to suggest and practise intrapulmonary injections as a means to attain this end. His method was used quite extensively for a time, but has now been practically abandoned. The results were not striking, the procedure was painful, and it has been displaced by other methods. The injections were made directly into cavities, with the purpose of disinfecting them and acting immediately on the contained bacilli. I have repeatedly seen a marked diminution in the secretion of cavities as a result of these injections, and a consequent improvement in the general symptoms resulting from pus absorption. Injections into tuberculous lung-tissue, which was merely infiltrated and not broken down, have, in my limited experience with this method, produced no benefit.

In 1855 Brainerd of Chicago opened a cavity in a tuberculous lung through the thoracic wall. In 1873 Mosler of Germany opened, drained, and medicated cavities locally. Though surgical intervention in tuberculous disease can be, and is, undertaken to-day with much greater confidence and chance of success than in former times, the operations of pneumonotomy and partial pneumonectomy in tuberculous disease must necessarily have a very limited field of applicability; ordinarily they are not indicated when the patient is in a sufficiently good condition to stand them, and in advanced cases they are but a forlorn hope at best. The recourse to surgery in diseased conditions is, after all, but a confession on our part of our limitations; and while we are compelled to admire the ingenuity and skill of the modern surgeon, and to be grateful that he can practically atone for the physician's shortcomings, surgical cures of disease are neither more or less than compromises.

Much was expected from the inhalation of antiseptics in tuberculosis. They were used extensively for a time, but have recently fallen into general disrepute. The form of inhaler usually employed has been so entirely inadequate to the requirements that little could be expected from it. The most popular in European countries has been some variety of the ori-nasal respirator, or some equally crude device, and the patient used it perfunctorily and without benefit. The amount of medicament capable of being administered by these means is insignificant, and probably does not reach further than the pharynx. The objections advanced against inhalations are that they do not reach the seat of disease, or, granting that they may, that the amount or concentration of the medicament used is too attenuated to be of value. That these criticisms of the ordinary respirator, or portable inhaler, are perfectly valid is undeniably true, but they can scarcely be advanced in regard to the vaporizing spray-inhalers which are used by many physicians in this country, and particularly when they are employed with some form of compressed-air apparatus, as in Evans' latest inhaler, Waldenburg's gasometer, or the pneumatic cabinet of Williams.

Protracted, continuous inhalation of medicines thoroughly nebulized under high pressure must necessarily bring them into contact with the entire pulmonary mucous membrane. While, of course, a few respirations do not carry the nebulized medicament into the finer tubes or alveoli, after breathing such a vapor exclusively for a length of time the residual air must become impregnated with it. The experiments of Arnold, previously mentioned,[28] demonstrate that dust *does* penetrate to the bronchial glands, and there seems to be no rational refutation of a similar action on the part of any other physical substance in a much more finely subdivided state. As regards the degree of concentration of antiseptics which can be administered, it is quite possible to give inhalations of a thirty-per-cent. solution of pure carbolic acid, or of the essential oils, like eucalyptol, *without dilution.*

Cough can be controlled and the lungs freed of accumulated secretions much more effectually by appropriate inhalations than by means of any medicines given internally. While there is very little probability that antiseptic inhalations have any distinct effect on the tubercle bacillus, it is quite easy to demonstrate that they do influence, very materially and definitely, the course of phthisis as we see it clinically. They modify or neutralize the effects of pus absorption. A sufficiently long inhalation will reduce a pyemic temperature almost as promptly, much more lastingly, and with infinitely less general depression than any of the antipyretic drugs, and this effect can be uniformly relied on. If these claims are susceptible of substantiation, as I believe they are, then certainly antiseptic inhalations have a position in the therapy of tuberculosis as enviable as anything can be short of a specific. Inhalations, properly employed, tend to relieve cough, aid expectoration, and control septic fever, and, in view of these capabilities, and by reason of the improvement in the nutrition of the lungs from the coincident exercise, I believe we can say that their influence is actually curative, though, of course, indirectly so. Trudeau used, for a time, inhalations of the vapor of hydrofluoric acid, and claimed to have distinctly affected the bacilli.[42] Hot air inhalations, with a view to their bacillicidal action, had quite a vogue a few years since. The results were *nil*, for it was soon proven that by the time the inspired air had reached the pharynx it had cooled to the temperature of the surrounding tissues. Gaseous inhalations have been popular and of considerable benefit in certain conditions. Valenzuela[43] advocated inhalations of sub-oxygenated air, as lessening the hyperoxygenation of the blood and the increased tissue-waste in florid conditions, and claimed by admixture of certain proportions of carbon dioxid to exactly reproduce the effects of varying degrees of altitude. In appropriate doses carbon dioxid is not poisonous and it is said to have the power of producing cicatrization of cavities and ulcerations.. Nitrogen monoxid is a constituent of the so-called "Compound Oxygen," and its anesthetic and sedative properties make it often of decided benefit. Bergeon's plan of gaseous enemata certainly was valuable, though disagreeable and complicated in its application. Inhalations of chlorin have been used, off and on, since the beginning of the century, and, in recent years, have been employed with benefit as part of the treatment of Shurly and Gibbes. Of more recent date is the procedure advocated by Carasso of Genoa,[44] consisting of continuous inhalations of oil of peppermint, with creosote internally, combined with super-alimentation. His conclusions seem to have been gratifying to himself, but the method has been without startling results in the hands of others. Hauke in 1870 constructed the first machine for the inhalation of compressed air. It has had many successors more or less elaborate. Among the most valuable is undoubtedly the pneumatic cabinet of Williams, which came into general use in 1885. At first it excited a great deal of interest and discussion, but gradually lapsed into oblivion (except in the work of some few men), quite as undeservedly as many other valuable discoveries. After nearly eight years of almost daily use I can quite agree with Quimby[46] that it is capable of immense benefit if it is used judiciously and with due appreciation of its capacities. Waldenburg's gasometer apparatus is also of decided value in certain cases.

Intratracheal injections have been employed with a fair amount of success in many instances. They seem to have a somewhat similar action to antiseptic inhalations, and have the advantage of not requiring so much cumbersome apparatus. I have used them with apparent benefit on many patients, and usually employ a solution of guaiacol and menthol in sweet almond oil. (See article by Barton.[45])

In the treatment of tuberculosis of the upper air passages the achievements of Herying and Krause, by curettage and excision of involved areas and the application of lactic acid, have enabled us to treat, with a large chance of success, the hitherto intractable and terrible lesions which occur in the pharynx and larynx. In our own country, Gleitsmann[47] has probably done more successful work in this direction than any of his colleagues. The method of direct injection of creosote into diseased tissues, proposed and practised by Chappell of New York,[48] has been, in many instances, brilliantly successful.

The hyodermatic, or more properly, intramuscular injections of medicaments seem in the main to have as their object the stimulation of leucocytosis and phagocytosis. Among them are to be mentioned Liebreich's injections of cantharidinate of potassium,[49] the Shurly-Gibbes injections of iodin and bichlorid of gold,[50] Landerer's injections of cinnamic acid,[51] and Edison's recent Aseptolin, beside a host of others. Vaughan's elaborate researches on the nucleins and their therapy are in the same line.[52] Iodoform, ichthyol, creosote, guaiacol, and most of the modern antiseptics have been used in the same way, and with varying degrees of success. The antithesis of hot air inhalations—persistent and continuous lowering of the body temperature—has been advocated for its theoretical bacillicidal action by Reed, who gives antifebrin as often as the temperature reaches 101° F.[53]

The drug most widely used to-day in the internal treatment of tuberculosis is creosote or some of its derivatives. It was first systematically investigated and brought to the attention of the profession by Sommerbrodt.[54] It is of undoubted value, though its exact status and the preferable preparation is not settled, but it is very questionable that it exerts any direct influence on tuberculosis.

Perhaps the first attempt to directly affect the bacillus by the influence of bacteriological products was made by Cantani of Naples who endeavored to attain this result by inhalations of cultures of the bacterium termo.[55]

Before Koch's announcement of the results of tuberculin therapy several observers had remarked a modification of the tuberculous process from thorough and repeated vaccination. The enthusiasm caused by the first exploitation of tuberculin, the subsequent distrust and disappointment, and its final repudiation by the profession at large, are of too recent occurrence to make it necessary to recall them. That the wholesale rejection of Koch's theories was as unjust and illogical as their first pyrotechnical acceptation is evidenced by the results of the work of a few conscientious, careful men in our own country, who have not allowed themselves to be swayed by popular clamor, but have determined to find out the truth for themselves. The efforts of Klebs to prepare a serum free from the objections of the first crude preparations have given us tuberculocidin and antiphthisin, each an improvement on its predecessor. They have been used by many clinicians with most promising effects. Among our compatriots Denison,[56] Trudeau,[57] and Von Ruck [58] [59] [60] [61] lead in their results. In his Sanitarium at Asheville, N. C., Von Ruck has used these products extensively and with effects which, if they are not yet *brilliant*, are most promising for the future. That in the line of the work that he is doing, with facilities equaled probably by none in this country, will be found (if it is not *already* found) a specific for tuberculosis, is a hope that is not entirely utopian.

Specific medication naturally applies only to a particular, definite, uncomplicated, pathological condition, and therefore it is well to remember in our search that we must not neglect, in striving for our comprehensive, all-embracing, ideal remedy, the broad principles of general treatment, as well as the minute details which will help our patients (very possibly cure them), until the remedy shall be given to us.

The modern treatment of tuberculosis presents itself to my mind with a double side: (1) That we must by all our resources, pre-natal, prophylactic, hygienic and sanitary, limit, and perhaps finally eradicate, the disease. (2) When it does occur, that we must use every endeavor by means of inhalations, injections, internal medication, climate, diet, *anything*, *everything*, which we can command, to eliminate the complicating infections and leave the tuberculous process to be dealt with by the specific which *will* come, if it is not already here. *Then* tuberculosis will lose its terrors, and the names of Koch and his co-workers and successors will be transmitted to posterity, as the greatest benefactors humanity has ever had. By means of sanitation and of serum-therapy (undoubtedly *the* therapy of the future), mankind will, at last, reach a point where (barring fortuitous accidents) the alloted span of life will be achieved, and the end of each human being will be Euthanasia.

EXPLORATORY INCISION IN THE TREATMENT OF CLOSED FRACTURES AND DISLOCATIONS.[1]

By JOHN B. ROBERTS, M.D.,
OF PHILADELPHIA, PA.;
PROFESSOR OF SURGERY IN THE PHILADELPHIA POLYCLINIC,
AND THE WOMAN'S MEDICAL COLLEGE OF
PENNSYLVANIA.

COMPLETE reduction, exact restitution of contour, and perfect retention, are the conditions of full success in the treatment of fractures. Deformity, impairment of articular movement, non-union, and neuralgic pain are remote results of failure to obtain these desirable conditions. Since aseptic surgery has made possible the prevention of infective inflammations in most open fractures, it is quite probable that better reduction, coaptation, and retention result in open than in closed fractures of the same grade and character of bony lesion.

The recent application of skiagraphy to surgical diagnosis has proved that fractures seemingly well reduced and properly dressed with splints may be the seat of considerable deviation from the normal skeletal relations. At the Polyclinic Hospital recently, for example, a fracture of the middle of the radius, supposed to be well reduced and dressed, was shown, by the use of the Röntgen ray, while the splints were in position, to have its fragments overlapping to the extent of about half an inch. In another case a painful swelling at the seat of a former injury to the fibula was discovered to be due to unrecognized non-union at that point. The rigidity of the tibia prevented the lack of union of the smaller bone being detected, but skiagraphy showed it plainly.

Nearly twelve years ago I advocated conversion of closed fractures of the cranium into open fractures by incision of the scalp, whenever uncertainty as to the character of the cranial lesion was prejudicial to intelligent treatment.[1] As part of my argument I said that no surgeon would hesitate to convert a closed recent fracture of the thigh or leg into an open one if it were impossible to replace fragments which were threatening life. I admitted that closed wounds are less serious than open ones, but asserted that with modern surgical methods, open wounds are preferable to closed wounds having inherent dangers that cannot be recognized without opening them. Further consideration and experience convinced me that this method should be extended to fractures in the limbs, even when life was not threatened, if obscurity of lesion or difficulty in reduction jeopardized function. Accordingly, a few years later,[2] I gave it as my opinion that recent fractures of the lower end of the humerus might with propriety be subjected to exploratory aseptic incision, if satisfactory coaptation was not obtainable under anesthesia; and that such action, though it involved opening the elbow joint, was as legitimate in properly selected cases as the recognized exploratory incision made in obscure abdominal conditions.

My belief in the propriety and value of exposure of the fragments in a certain limited number of closed fractures has been strengthened as years have passed. The method, which I do not claim as novel, has, however, not been sufficiently impressed upon the profession to cause its adoption by surgeons in general. Allis of Philadelphia has advocated it[3] in rebellious fractures of the upper third of the shaft of the femur, in order to apply steel screws for retentive purposes. In England, Lane has employed it[4] in oblique fractures of the tibia and fibula near the ankle, for the same reason. McBurney[5] and others have resorted to it in fracture of the upper end of the humerus complicated with dislocation. Dennis[6] and Ricard[7] also approve of it in cases where there is difficulty in obtaining correct apposition of fractures. Other writers may have mentioned the subject, and cases may have been occasionally reported; but, except in fractures of the cranium and patella, I think that most surgeons are more apt to be satisfied with imperfect results than to advise immediate exposure of the fragments before the patient comes out of the anesthesia induced for the purpose of examining and reducing the fracture.

---

[1] Prepared for the Second Pan-American Medical Congress, November, 1896.

This attitude of the profession in general has been evident in societies at which I have incidentally mentioned my views;[8] and is due to conservatism bred by the fear of open fractures felt by all in the pre-antiseptic period of surgery. The method has suggested itself to many practical surgeons, but it needs to be ever before our minds as a legitimate procedure.

My advocacy of cutting down upon closed fractures is limited to cases in which ignorance of the exact lesion, impossibility of reduction, imperfect immobilization, or failure to deal efficiently with complicating lesions makes the incision the less of two evils. An aseptic incision is almost devoid of risk, even if it opens a joint; but that slight risk should not be added to the patient's burdens unless the probability of deformity, of interference with joint movements or other functions, of pain, of paralysis, or of non-union justify it. Here, as in all departments of surgery, it is the surgeon's duty to exercise care and good judgment in selecting the method of treatment. To illustrate my meaning I cite fracture of the patella, which I have never treated by incision and suture of the bone, because I have thus far always been able to satisfactorily bring the fragments together by hooks, subcutaneous suture, or splint. In one or two instances I have almost decided to lay open the overlying tissues in order to obtain approximation by direct appliances, but I have finally not been obliged to do so. The open operation I believe to be legitimate, and probably needful in a very few selected cases, but I am opposed to it as a routine treatment.

It is self-evident that the wound exposing a fracture must be aseptic, and that the operator who adopts incision must be familiar with the steps to be pursued at the inception of infective inflammation. A man who will hesitate to reopen the wound or drain the joint, at the moment septic premonitions show themselves, should associate a more energetic surgeon with himself in such operative treatment of fractures. The risk of incising muscles and opening joints, if done in an aseptic manner by an operator familiar with truly aseptic and antiseptic surgery, is unquestionably very slight. Primary union without disturbance of joint-function will be almost universal.

If it once be admitted that the seat of a fracture can be exposed by incision, with little or no risk to life, there are many advantages that will at once suggest themselves:

1. The exact lines of separation can be seen, and the significance of lines of comminution in relation to subsequent reconstruction can be fully appreciated.

2. Coaptation need no longer be guessed at by the sensations imparted to the examiner's fingers, separated as they are from the bone by varying thicknesses of muscle, fat, and skin; nor need it be dependent upon the possibility of having conveniences for taking a skiagraph.

3. The fragments can be accurately fitted together, torn periosteum replaced, and muscular and fascial bands, nerves and muscles disentangled from undesirable positions between the pieces of broken bone. This prevents deformity by permitting restoration of normal contour of the limb, and lessens the occurrence of non-union, neuralgia, atrophy, and ankylosis.

4. When the osseous, muscular, and vascular relations have been restored, they can be perfectly maintained by the application of sutures, pegs, nails, screws or ferrules to the bone, and sutures or ligatures to the muscles, nerves, and vessels.

5. The pain, due to extravasation of blood, rapid inflammatory exudation or traumatic synovitis, is relieved by the removal of the clots and leaking out of exudation and synovial fluid. The interstitial pressure caused by extravasated blood and exudate has often heretofore caused surgeons to split the skin and deep fascia by long incisions, in very bad fractures, in order to avert threatened gangrene. A similar relief of tension in less urgent cases will undoubtedly lessen pain and suffering, though such operative treatment would ordinarily not be adopted. The incisions employed to uncover the fractures are therefore indirectly of value as relievers of pain.

6. Pain is also lessened, in the few cases requiring direct retentive apparatus, because the sutures, nails, or screws prevent motion between the fragments better than external splints. Muscular spasm or incautious movement has therefore little opportunity to cause suffering.

7. Fat embolism is probably less likely to occur in fractures liable to its occurrence, if early escape for the fatty *débris* is permitted by incision.

8. Ankylosis from faulty position of fragments, irregular formation of callus due to stripped up periosteum, and gluing down of tendons, will seldom occur after the fracture has been disclosed to the scrutiny of a competent surgeon.

9. Repair of the broken bone and functional restitution of the surrounding tissues occur more rapidly than when coaptation is imperfect, or when damaged, muscular and other structures are left to the unaided efforts of nature. Impairment of digital movements after fractures is probably often due to coincident rupture or laceration of muscles, which

might have been repaired by suturing with catgut, if the surgeon had known of the existence of the complication. The aseptic wound affords him this opportunity; and afterward usually heals so rapidly that it is of no disadvantage to the patient's period of convalescence. This early restoration of wage-earning capacity is of great value to many patients.

10. It not infrequently happens that a closed fracture seems to have been well set, and to have left little deviation from the normal; and yet the patient has lost some of his availability as a machine. This is most likely to occur in the lower limb which, during locomotion, carries the entire weight of the man. A slight change in the axis of a bone or in the plane of an articulating surface may perhaps throw the weight upon the hip, knee, or ankle in an abnormal way and induce a considerable and ever increasing disability. This contingency is usually avoidable after the accurate inspection of the injured bone permitted by uncovering the fracture by incisions.

In vicious union of fractures due to absence of treatment, or to injudicious treatment, I believe that it is sometimes much better to expose the seat of deformity and divide the deformed bone with an osteotome than to refracture subcutaneously by an osteoclast or the surgeon's hands. Many cases can indubitably be well treated by refracture without incision or by subcutaneous osteotomy; but if there be a reasonable doubt as to one of these methods enabling the surgeon to accomplish relief of the deformity, free exposure, such as I have just been advocating in recent fractures, is the proper treatment.

A similar method of dealing with luxations which are not readily reduced by manipulation under anesthesia is, in my opinion, preferable to a long continuance of unsuccessful manipulations, the application of great power by apparatus, or a relinquishing of the attempt to restore the integrity of the joint. It is true that in all dislocations, except those of the spinal column and the backward luxation of the second phalanx of the thumb, reduction is usually readily accomplished by skilful manipulation under anesthesia, provided the attempt is made while the injury is recent. My contention is that in recent dislocations, when this is not the case, and in old dislocations, arthrotomy should be promptly done. No surgeon would recommend allowing the displacement to remain without attempting reduction; and I believe that compound pulleys or other methods of applying great force are usually more risky than prompt and thorough exposure by incision. Immediately before making the incision it would be well in most cases to make a final effort to reduce by manipulation; but this should not be carried to a sufficient extent to cause much bruising or muscular laceration. The presence of such traumatism would increase the liability to septic processes, if imperfect asepsis allowed germs to gain access to the wound during the operation.

Arthrotomy for irreducible dislocation is not a novel suggestion, for it has been repeatedly done by many surgeons in old injuries. It has not, however, I think, been often adopted until after vigorous efforts have been made to subcutaneously replace the separated articular surfaces. Its use in luxations a few hours or a few days old, except perhaps in the fingers and toes, is probably almost unknown as an accepted surgical procedure. I believe it ought to be the approved treatment in a small number of cases. The advantages of the open method will at once be patent when the accidents that occasionally follow the employment of the older methods are recalled. Fracture of the bone or laceration of artery, vein, or nerve, is only likely to occur when the region is not exposed to the operator's eye, In case of impossibility to properly reduce the dislocation, moreover, the end of the luxated bone can be excised. This will probably nearly always give a better functional result than to allow the previous condition to persist. Excision is not infrequently required after attempts to reduce old luxations without incision have proved unavailing. In an attempt to reduce an old luxation of the humerus I have displaced the head of the bone in such a way that it rested on the brachial plexus and caused more trouble than the original deformity. This would not have been the result, I think, if I had exposed the luxated bone by arthrotomy. If the open treatment is to be adopted it is evident that the patient will receive the greatest advantage if it be instituted before the head of the bone is altered in shape, the socket changed, and muscles and fasciæ contracted or adherent to surrounding tissues. The open method in addition gives opportunity to divide any ligaments, tendons, fasciæ and muscles which restrain reduction, to scrape out any material filling the socket, and to make provision for preventing recurrence of dislocation by retrenching the capsule or other plastic measures.

Skiagraphy may have a field in this department of surgery, as in fractures, by indicating the character of the luxation before the incision is made. It may perhaps be urged to this plea for a more general employment of exploratory incision in closed fractures and dislocations that there are great objections to making a closed lesion of the osseous system an open one.

I know of no objection except the risks inherent in anesthesia, the possibility of infection, the occurrence of serious bleeding, and the production of ankylosis. The objections are of no force when the injury is one requiring exploratory incision. Anesthesia will have been used in such instances for diagnosis or attempted reduction. Its moderate prolongation for the necessary time will add practically nothing to the risk. Bleeding is no contraindication except in that rare condition, hemorrhagic diathesis. Ankylosis is more liable to occur from displaced fragments or articular surfaces, irregular callus due to stripped up periosteum, and interference with articular contact, than from aseptic incision into the joint and readjustment of the joint structures. The possibility of infection is, then, the only factor that requires consideration. Fifteen or twenty years ago, even subcutaneous tenotomy at the heel, recommended by the surgeons of the Pennsylvania Hospital in cases of marked displacement after fractures of the tibia, was undertaken with some hesitation. Now operative infection in muscular and osseous lesions is so preventible and so readily managed by prompt action that it is no longer a valid objection to incision in a closed fracture or dislocation, if functional disability is liable to occur unless this operation is performed. For some years it has been the practice of surgeons to incise open fractures freely in order to thoroughly cleanse the deep recesses, obtain an antiseptic condition of the lesion, and get rid of effused blood. An extension of operative surgery is, in my opinion, now warranted in closed fractures and dislocations in which ordinary methods of reduction prove unavailing or unsatisfactory.

A FURTHER CONTRIBUTION TO THE STUDY OF THE FAMILY FORM OF SPASTIC PARAPLEGIA.

BY LEO NEWMARK, M.D.,
OF SAN FRANCISCO.

IN the *American Journal of the Medical Sciences* for April, 1893, the present writer described two families, in each of which there were children afflicted with a spastic condition of the lower extremities. In one of these families the spastic rigidity was observed in three brothers, in unequal degrees, and it was also remarked that some of the other children exhibited more or less excesssive tendon-reactions. The note referring to one of these reads thus: "Maggie, aged six years. According to parents has, habitually, 'a lazy, dragging walk.' Knee-jerks much increased; slight ankle-clonus could be elicited, but with difficulty, as the child could not be induced to relax the muscles. Tendon-reflexes of upper extremities are present, but not excessive. Jaw-jerk quite active."

The child was still in this condition in June, 1893; there was nothing in her manner of walking or her attitude to attract attention. When seen again in March, 1894, she was found to be affected with pronounced spastic paraplegia. The mother related that the patient had been well until August, 1893; she then contracted bronchitis, and at the same time her gait became impaired, the present condition of the legs developing very rapidly. No reliable statement could be elicited as to the exact mode and rapidity of the onset. The bronchitis was followed by whooping-cough. Before this illness the patient had been a cheerful child, but since then had been depressed and taciturn.

An examination in March, 1894, showed her to be pale and dejected. She coughed and had a temperature of 100° F. at noon. There were bronchitic râles and enlarged cervical glands. She was unable to walk without assistance, but when supported she could walk with the typical spastic gait, shuffling along on her toes. The tendency to the equinus position was a little more marked in the right foot than in the left. As far as her limbs are concerned her condition then was, on the whole, the same as at the last examination, on the 20th of December, 1895. On this day it was observed that she had regained her general health. While seated she exhibited no spasm of the adductors or rigidity at the knees The big toe of each foot tended to hyperextension. She was able to stand for a minute or so without aid, holding the trunk inclined forward, the hips and knees flexed, the thighs adducted and the heels drawn up. She walked stiffly and laboriously, if held by the hand, scraping the floor with the tips of her shoes. The nutrition of the legs was normal. The knee-jerks were greatly exaggerated. The tendo-Achillis-jerk was in excess: a single tap on the tendon sufficed to produce several alternations of extension and flexion of the foot. By tapping the right tendo-Achillis a few times in rapid succession before flexing the foot, prolonged ankle-clonus was produced, which lasted as long as the flexion was maintained. On the left side only very brief clonus was elicited. The plantar reflex was very faint.

In the upper limbs the tendon-jerks were exaggerated; no clonus was obtained. The jaw-jerk was present. Sensation, the functions of the bladder, and the pupils were normal. There was neither strabismus nor nystagmus. In the right cornea there was a leucoma.

It will readily be conceded that the disease of this girl is the same as that with which her three brothers are affected. It is a spastic condition of the lower extremities, and it is the rigidity rather than any diminution of motor power that interferes with locomotion.

Erb[1] has published an account of two sisters, both of whom presented essentially the same clinical picture as these children, under the title of "Hereditary Spastic Spinal Paralysis." Strümpell[2] employs the same term for a spastic disorder observed by him in two different family groups, which, however, varies from that seen in Erb's and my cases in certain particulars. Indeed, within the last few years the multiple occurrence of spastic disease in families has been observed in a not inconsiderable number of instances[3], the classification of which is often rendered difficult by the variations they exhibit in respect to the age of onset, the progressive tendency, the range of symptoms, and other features.

Thus, while in some the spastic rigidity of the extremities is the sole manifestation of the disease, and might be referred to a morbid process in the lateral columns of the cord; in others, superadded muscular atrophy, inco-ordination or vesical debility would indicate a more extensive involvement of centers or strands in the spinal marrow, and in still others the associated symptoms would point to the brain as being primarily the defective organ. The anatomical data are by far too scanty to furnish a basis for classification.

The multiple occurrence of a disease in families is generally considered to be evidence of its endogenic nature. The resemblance of some of the cases of spastic rigidity occurring in families to "Little's disease" is, however, so great as to prompt inquiry into the conditions of the patient's birth and to sometimes suggest the dependence of their affection on the reiterated action of the etiological factors detected by Little in the abnormalities of labor rather than on a congenital tendency. In my former article I mentioned in this connection the cases of Schultze: Two brothers and their sister were each born at term, or after a somewhat longer period of gestation than usual; the births are said to have been slow and difficult, lasting three days in each case, but no artificial manipulations were resorted to —in fact, no medical aid was summoned. After delivery, it is stated, there was nothing to indicate that the infants had sustained any injury, and their development seemed normal until the age at which they should have walked, when the spastic rigidity of their lower limbs became obvious. An elder sister, the first-born child, was born without difficulty and remained well.

These cases are considered instances of "Little's disease," of cerebral birth-palsy, by Shultze and most authors who have occasion to comment on them. But it seems more plausible to me to classify them with the increasing number of very similar cases for which only a congenital tendency, peculiar to their family, will account. Wherein the "difficulty" of the births consisted, is not related; it is alleged that labor was prolonged, but we are allowed to infer that there was no asphyxia, there were no convulsions, no evidence that the duration of parturition had been disastrous to the children's brains. The easy birth of the first child would serve to indicate that there existed no structural abnormality in the mother sufficient to so impede labor as to cause a grave injury to the nervous system of three of the subsequent offspring.

B. Sachs[1] concurs with Schultze in regard to the etiology of the latter's cases, and therefore refuses them consideration in the chapter on "Hereditary Spastic Paralysis." He concedes to instrumental delivery some influence in the production of the disease, also, in the three brothers of my patient described in the foregoing, and while admitting "that there is a tendency to spastic paralysis in this family," yet he thinks "the fact that instruments were used at the birth of several children, including the one whose symptoms were most pronounced, makes it probable that 'heredity' alone was not responsible for the multiplicity of cases."

The assumption that the use of instruments may have been partially responsible for these cases is founded on nothing more than their external resemblance to a certain form of "Little's disease," and it is an unnecessary assumption, the tendency to spastic paraplegia being granted. At two of the births, moreover, no instruments were employed; and even if they had been the mere employment of them would not imply that disaster must follow on each occasion; nor would years have elapsed before the damage became evident.

The spastic condition of the children in the two families described by me conforms to what has been called "the spinal type of hereditary spastic paralysis." By the kindness of Dr. H. M. Sherman, orthopedic surgeon to the Children's Hospital, San Francisco, I am enabled to report the history of two sisters, in a third family, who, besides an incipient spastic affection of the lower limbs, exhibit defective development of the power of speech. I have had only one opportunity of observing these cases, and plead this as an excuse for the incompleteness of the account of them.

[1] *Deutsche Zeitschrift für Nervenheilkunde*, Bd. VI.

[2] *Deutsche Zeitschrift für Nervenheilkunde*, Bd. IV.

[3] Higier recently collated the literature of the subject and added new observations in the *Deutsche Zeitschrift für Nervenheilkunde*, Bd. ix., H. 1. Since the publication of his article, Raymond and Souques (*Semaine Médicale*, August 8, 1896) have reported the cases of two sisters with progressive spastic paraplegia. The disease began in the elder, at the age of nine years, in one of the lower extremities, and then progressed until it involved both legs in a high degree, and also, in a less degree, the upper limbs and the trunk; in the younger girl, who had been affected since the age of twelve years, the lower limbs only were involved. The birth of each had been normal.

[1] "Nervous Diseases of Children," page 393.

No nervous disorders are known to have occurred in previous generations of this family. The father is said to be temperate in the use of alcohol, but to smoke cigarettes to excess. He is employed, like the father of the other children with which this paper deals, in the gas-works. He is reported to be normal, except that he has a "cast in the eye." The mother enjoys good health. She has had no miscarriages. The parents are not related by blood.

There have been five children. The eldest, Edith A., twelve years old, is well. She began to walk at the usual age. At her birth the forceps was used, merely to curtail labor, it seems. The second and third child died at four and two years respectively, both in the same week, of diphtheria. They had talked and walked well.

The fourth child, Emma A., is six years old. She was born at term; labor was easy, but was terminated by forceps by the same attendant as at the first birth. The infant was not asphyxiated, and had no convulsions. She thrived, and made her first attempt to speak at one year, but her articulation has remained very indistinct. The grandfather declares that he understands her with great difficulty. When two years old, the patient had scarlet fever, and the mother thinks that after that the faculty of speech was still more impaired. Two months before the visit, a stiffness of the legs and a tendency to raise the heels were first noticed.

Condition August 24, 1896.—In the room the patient stands, walks, and runs about actively, but close inspection reveals a decided inclination to pes equinus on the left side; the shortening of the tendo-Achillis is undoubted. There is slight rigidity at the knees. No ankle-clonus. Achillis-reflex present; also plantar-reflex. The knee-jerks are greatly exaggerated. Tapping on the anterior tibial region causes the whole leg to jerk. The big toes are now and then over-extended. Active jerks are easily elicited in the upper limbs—more active than normal. A plain jaw-jerk may be provoked.

The fifth child is Margaret A., four years and three months old. Born at term; no instruments employed. There was another attendant at this confinement. No asphyxia, no convulsions. Has had no illness except the present trouble. Began to say "mamma" and "papa" at one year, but her articulation remained very indistinct, and it is only of late that her mother has been able to understand her. Walked at fourteen months. Six months ago the tendency to walk on her toes became manifest, and it has been more pronounced since last May. Frequently catches her toes and trips, sustaining bruises. Wears her shoes out at the tips.

Condition August 24, 1896.—Very slight strabismus. The spastic condition of the lower extremities, although more pronounced than in her sister, is not sufficient to prevent active locomotion. Raises the heels when walking. There is incipient shortening of the tendo-Achillis. No foot-clonus. Great exaggeration of knee-jerks, which are easily provoked by tapping anterior tibial or femoral region. The plantar reflex is present. There is a tendency to over-extension of the big toes. Active jerks produced in upper limbs. A slight jaw-jerk is obtainable.

Both children use their upper extremities freely. At the examination they were noisy and unruly, but it was ascertained that they presented no disturbance of sensation. Their general nutrition and that of their legs, particularly, is good. It was difficult to form an accurate opinion as to the extent of the defect in their speech; an occasional expression indicated that they have some power of speech and that they are not idiotic. Indeed, they are considered intelligent by their mother and maternal grandfather. They have control of bladder and rectum, and are cleanly in their habits.

The association of defective speech with the spastic rigidity of the limbs ranks these cases with those of a cerebral or cerebro-spinal type. For the present, one must be content to merely record the cases and await the results of anatomical investigations before attempting further interpretation of the symptoms.

SYMPHYSEOTOMY FOR THE RELATIVE INDICATION.

By EDWARD P. DAVIS, A.M., M.D.,
OF PHILADELPHIA;
PROFESSOR OF OBSTETRICS AND DISEASES OF INFANCY IN THE
PHILADELPHIA POLYCLINIC; CLINICAL PROFESSOR OF OBSTETRICS IN THE JEFFERSON MEDICAL COLLEGE,
AND MEDICAL DIRECTOR OF THE JEFFERSON MATERNITY; VISITING OBSTETRICIAN TO THE PHILADELPHIA HOSPITAL,
ETC.

WHILE there may be room for discussion regarding the positive indications for symphyseotomy in some cases, this operation is clearly required in cases where disproportion between the fetus and the pelvis exists, the pelvis itself being but little, if any, smaller than the average. The results of the operation in these cases are best, especially in multiparæ, in whom the genital canal has been previously dilated by childbirth, but in whom the progressive increase in the size of the fetus, seen in repeated pregnancies, is also a complicating factor. The prognosis in such a case depends very largely upon the presence or absence of infection, and whether or not the patient has been already subjected to fruitless efforts at delivery before the operation is undertaken. These statements find illustration in the following case:

The patient, Mrs. M. K., was brought by ambulance to the Jefferson Maternity on January 21, 1896, with the following history: She had been delivered, some years previously, of a living child, by forceps, after a tedious extraction. Her general appearance was that of good health, and she was fully of average size and development. The present pregnancy was her second, and she had come into labor at full term, the child being evidently large and well developed. Spontaneous labor failing, the physician in attendance had summoned assistance, and forceps had been applied unsuccessfully. The presentation and position had seemed favorable for forceps delivery, but her physician had desisted, and had sent the patient to the Maternity. On admission, her general condition was fairly good. Palpation revealed the fact that the head had but partially engaged. The child was living, and occupying the second position. The mechanism of labor had paused at the stage of partial engagement. The heart-sounds were very rapid. Pelvimetry revealed the size of the pelvis as follows:

Anterior superior spines . .	24 cms.
Crests	25 "
Trochanters	30½ "
External conjugate . . .	19¾ "

The child was evidently larger than the average, the complication being disproportion between the mother and child, with but a slight contraction of the pelvis.

The husband and mother of the patient followed her to the Maternity, and it was stated to them that in the interests of the mother and child, symphyseotomy was clearly indicated. A guarded prognosis was given because of the previous attempt to deliver with forceps, and the danger of infection which it entailed. The patient had been in her own dwelling, and without the services of trained nurses. The operation itself was performed without difficulty; the symphysis was readily opened by an incision through the abdominal wall, terminating a half-inch above the joint, the joint itself being opened by a probe-pointed bistoury passed along the fingers which protected the urethra. After symphyseotomy, it was found that the occiput had rotated posteriorly, and the child was readily delivered in this position with Tarnier's forceps. It was noticed that a very perceptible odor was present when the child emerged.

The child was a male, weighing 8 pounds; 50½ cms. long. The measurements of its head were as follows: Maximum, 15½ cms.; occipito-mental, 14 cms.; occipito-frontal, 13 cms.; suboccipito-bregmatic, 12 cms.; biparietal, 10½ cms.; bitemporal, 9½ cms.; bisacromial, 13½ cms. The placenta weighed 1⅛ pounds; the length of the cord was 23 inches. The child's respirations were exceedingly rapid, varying from 40 to 60, and it was evident that inspiration-pneumonia had begun. The child survived delivery eighteen hours, perishing from pneumonia.

On examining the mother it was found that slight lacerations of the anterior and posterior vaginal wall had occurred, requiring suture; these were closed with chromicized catgut, the uterus freely douched with an antiseptic solution and tamponed with iodoform gauze. The symphysis was drained for twenty-four hours by a packing of iodoform gauze, while the bladder was continuously drained by permanent catheter for several days. The patient rallied well from the operation, but gradually developed a sapremic condition. This necessitated a thorough cleansing of the uterus with the douche-curette, after which her symptoms decidedly improved. Union occurred through the greater portion of the symphyseotomy-wound by first intention. Immediately above the pubes suppuration in the cellular tissue occurred, and a slight discharge of thin pus persisted for several days. This was readily drained by a light packing of gauze. Union occurred, without interruption, in the joint, the patient ultimately making a perfect recovery. She was kept at the Maternity seven weeks after admission, in order that her convalescence might be completely assured. She was then in excellent condition, able to walk on a level, and up and down stairs without discomfort. Her pelvis had united firmly, and the genital tract was in normal condition. Ten weeks after the operation her pelvis was measured, with the following results:

Anterior superior spines . .	24½ cms.
Crests	25½ "
Trochanters	31 "
External conjugate . . .	19¾ "

Comparison with the measurements made on admission shows a gain of ½ cm. in several diameters of the pelvis. This patient has been twice seen since her discharge, the last time during the month of October, 1896. She is in perfect health, and has not experienced the slightest inconvenience from the pelvis or pelvic organs.

The method of treatment employed for immobilizing the pelvis is that which I have found sufficient in seven symphyseotomies. So soon as delivery is effected, and the genital canal made aseptic, and sutured, if necessary, the pelvis is brought together by firm pressure, and a strip of the best rubber adhesive plaster, from six to eight inches wide, is passed firmly around the pelvis, the center of the strip being over the trochanters. The usual occlusive dressing is placed over the vulva and over the symphyseotomy-wound. The patient's knees are bandaged together until she fully regains consciousness after the anesthetic. When it is necessary to clean the patient, she is carefully lifted by two assistants who grasp the pelvis firmly from each side. When the strip becomes soiled, it is removed, the skin carefully washed with soap and water, then with alcohol, and dusted with powdered oxid of zinc, or boracic acid. A fresh strip is then applied. Should it be desired to avoid disturbing the patient, a second strip can be applied over the first, should the first become stretched or moistened. A firm roll is placed beneath the patient's knees, her posture being most comfortable when the knees are partly flexed. The plaster dressing is worn for three or four weeks, when it is replaced by a canvas belt with buckles. Care is taken to cut out the plaster strip over the uterus, that it may not interfere with involution. In seven cases, good nursing and strict cleanliness have prevented the formation of bedsores. If the skin be bathed frequently, and alcohol be used in addition, patients should experience no trouble from the pressure of the bed or the constrained posture. This was the only case in which I have met with suppuration after symphyseotomy. The question occurred, so soon as pus was discovered in the joint, whether drainage would not be necessary by puncturing the anterior vaginal wall. It was observed that no active inflammation seemed present, and that the source of the discharge seemed to be the fatty and connective tissue immediately behind the joint. The gauze drain proved perfectly efficient, and the use of irrigation was not found necessary. So far as the ultimate result was concerned, the discharge from the joint seems to have had no bearing upon a perfect union.

In reviewing the case, the difficulties under which the physicians originally in charge labored must be kept in mind. In the ordinary dwelling, the circumstances are not favorable to a strictly aseptic operation, and especially in the absence of suitable nurses. While the physician himself may be thoroughly clean, it is almost impossible, without good nursing, to prevent infection in many cases. The interesting question arises, Was symphyseotomy justified, or should craniotomy have been performed? Here again, the experience of the writer is decidedly in favor of symphyseotomy, as this is the only case in seven in which the child did not survive. The careful examination of the child's head showed that injury to the cranium was not present. Inspiration-pneumonia was so clearly present that no reasonable doubt exists as to the cause of death. Had craniotomy been performed, the delivery would have been no less difficult, and the mother's genital tract would have been subjected to even more bruising than was present in the case. It was observed that as a result of the attempt to deliver with forceps the pelvic floor and vagina were considerably swollen when the patient was admitted. The heart-beat of the child on admission was sufficiently good to warrant an effort to save its life, and hence craniotomy was declined in favor of a conservative operation.

A Hospital for Children. — Baroness Hirsch is contemplating the desirability of giving 2,000,000 francs for the erection of a hospital on the Riviera for consumptive children.

CLINICAL MEMORANDA.

A CASE OF PERFORATING GASTRIC ULCER; OPERATION; RECOVERY.

By ANDREW J. McCOSH, M.D.,
OF NEW YORK.

In recent years considerable attention has been devoted to the surgical treatment of gastric ulcers, not alone in cases of perforation, but also when persistent pain and hemorrhage have baffled medical treatment. In the latter class of cases the possibility of failure to find the ulcer must always be considered before gastrotomy is recommended. In the former class, however, no question can arise as to the propriety of surgical interference. Gastric ulcer is a common disease, and perforation takes place in at least ten per cent. of the cases (Comte says in fourteen per cent.). Without surgical treatment more than ninety-five per cent. of these patients must die. In an admirable article[1] Drs. R. F. Weir and E. M. Foote have tabulated seventy-eight cases treated by operation (where perforation into the general peritoneal cavity had occurred), with a mortality of seventy-one per cent. This mortality, however, would undoubtedly be much reduced could the patients fall into the hands of the surgeon soon after the perforation. Take for example the twenty-three cases where operation was done within twelve hours (Weir and Foote's tables), and there were fourteen recoveries, a mortality of thirty-nine per cent.

The results of operative interfence in cases where a localized intraperitoneal abscess has formed without rupture into the general cavity must be still more favorable. In such patients an early diagnosis and an early operation are of the utmost importance. It is true that often the diagnosis is obscure, but even in doubtful cases the symptoms are generally such as to warrant an exploratory operation. The walls of such abscesses vary greatly in strength, and no one can predict how soon rupture will take place. In the case the report of which follows, the abscess had evidently existed for at least four weeks, and in spite of cathartics, gastric lavage, and vomiting, its walls had not yielded. At the operation this was explained by the large amount of inflammatory exudate surrounding the abscess cavity.

E. R., aged thirty-five; widow; never pregnant; absence of rheumatic, syphilitic, malarial, and alcoholic history. Has never suffered from typhoid, dysentery, or any of the contagious diseases. When twenty-one years of age she weighed 170 pounds. For years habitual constipation necessitated the use of cathartics every second or third day. During the past three or four years occasional attacks of severe constipation, when sometimes for weeks there would be no movement of the bowels. For the past eighteen months she has suffered from disturbances of digestion, occasional nausea and vomiting, with frequent severe colicky pains, and some abdominal distention. Considerable and progressive loss of flesh and strength. In September weighed 114 pounds. On October 24, 1895, attack of vomiting and nausea, continuing for two or three days, with abdominal pain, especially in the epigastric region. In spite of cathartics, persistence of obstinate constipation, so that until November 6th only one small movement of the bowels could be obtained. Abdominal distress increased and but little nourishment could be taken. On November 4th the epigastric pain had become so severe that Dr. R. Milbank was called in consultation by her physician. At that time the abdomen was considerably distended, the muscles rigid, and there was general tenderness, but more marked in the epigastric region. Dr. Milbank made the diagnosis of either perforating gastric ulcer, or partial intestinal obstruction due to a band, and advised laparotomy. He asked me to see the case on November 5th, and we agreed that the probable diagnosis was an ulcer of the stomach, which had either partially perforated, with a resultive local peritonitis, or had entirely perforated, with a resulting encapsulated abscess. Her temperature then was 101° F.; pulse, 100; respiration, 26. She complained of severe pain in the epigastric region, with exquisite tenderness, the most tender point being a little below and an inch to the left of the ensiform cartilage, and in this region an indistinct mass could be felt, though on account of the tenderness it was impossible to determine its nature or extent. Consent was not given to an operation. Between November 6th and 24th the patient was seen by a number of physicians, who were in doubt as to the nature of the trouble, and advised against immediate operative interference. During this time the epigastric pain continued, the abdomen remained moderately hard and tympanitic, nausea and vomiting persisted, but little nourishment could be taken, and there was a steady loss of flesh and strength. The bowels were moved by high oil enemata and gastric lavage was employed. There was continued fever; the morning temperature was 99½ to 100° F., the evening 101 to 102° F., occasionally rising as high as 104° F.; pulse, 110 to 130. She was afterward admitted to the medical division of the hospital, when the necessity of operation was urged by Dr. F. C. Kinnicut. On November 25th the patient was admitted to the surgical division. Abdomen hard and moderately tympanitic. Epigastric region very sensitive to pressure. Projecting from under the free border of the left costal cartilages, toward the ensiform cartilage, could be felt a resistance, and an indistinct mass which seemed immovable and apparently attached to the stomach. Temperature, 102½° F.; pulse, 110. In spite of adverse opinions the case was diagnosed as one of perforating ulcer of the stomach with an encapsulated intraperitoneal abscess. The history, the acute epigastric pain and tenderness, with the indistinct mass in this region, seemed to point to this conclusion. Another important sign was, that the pulsation of the aorta seemed to be transmitted directly to the finger, when gently placed on the surface of the abdomen just below the tip of the sternum. The impression was given that a solid body had taken the place of the hollow viscera, that it rested on the aorta, and was adherent to the abdominal wall. This peculiar pulsation is often a sign of great value when it is a question in diagnosis between cancer and tumors of an inflammatory origin.

---

[1] MEDICAL NEWS, May 2, 1896.

Operation. — November 26th; chloroform. Vertical median incision, 3½ inches downward from the tip of ensiform cartilage. When the peritoneum was reached, it was found firmly adherent to structures beneath. In the upper three-fourths of the incision was found the adherent left lobe of the liver, which was markedly congested. In the lower fourth was found the stomach adherent to the abdominal wall and to the liver above. This agglutination of stomach and liver formed the superior wall of the abscess. The liver was separated and pushed upward and the stomach pushed downward. Between these organs there was a considerable mass of inflammatory exudate. Through this material the finger was gently pushed, and at the depth of two inches a cavity was entered which contained about two ounces of frothy, purulent fluid, particles of coagulated milk, and remains of food. At the bottom of this cavity, at a point 3½ inches below the skin, was felt an opening into the wall of the stomach, which admitted the tip of the index finger. The opening was oval in shape, with indurated and comparatively smooth edges. For a considerable distance around this opening the wall of the stomach was thickened, and very markedly so, for a space the size of a silver dollar; its thickness at the edges of the opening being at least one-third of an inch. This opening was situated in the lesser curvature, just anterior to the attachment of the anterior layer of the lesser omentum, and at a point about one-fourth of the distance from the cardiac to the pyloric orifices.

The abscess cavity was carefully cleansed, the edges of the opening in the stomach were thoroughly scraped with a scalpel and trimmed with the scissors. The opening was then closed by two rows of sutures. The first row consisted of uninterrupted catgut sutures passed through the serous and muscular coats, both of which were much infiltrated with inflammatory tissue. The second row consisted of interrupted silk sutures inserted through the serous coat. The tissue was so friable that several of the sutures of each row tore out, and consequently it was necessary to introduce the needle at a considerable distance from the edge of the opening. After careful cleansing, a strip of sterilized gauze was passed down to the line of suture and the end brought out through the abdominal wound, the remainder of which was closed by three rows of sutures. Moderate shock followed.

November 27th: Patient complained of nausea, and there was slight vomiting. Temperature, 100½° F.; pulse, 110.

December 1st: External dressing changed; no sign of leakage. Temperature, 99½° F.; pulse, 110.

December 3d: Gauze strip removed; no leakage. Temperature has not reached 100° F.

December 7th: Attack of pleurisy, with effusion on *right side*, continuing with considerable severity for ten days.

December 20th: Sutures removed; gradual gain of strength; nausea disappearing and appetite returning; bowels move freely.

December 25th: Out of bed; fair appetite; progress very slow.

January 10th: Considerable gain of strength; discharged.

October, 1896: Since discharge, there has been slow but progressive gain in flesh and strength. For the first six months, appetite was very poor and digestion weak. For past three months, however, gain has been more rapid. Increase in weight since discharge from hospital, twenty pounds. General condition fair; no nausea or vomiting, but caution needed in the selection of her diet. No pain, and patient feels that she is slowly, but steadily, improving.

January 1, 1897: Gain of ten pounds in weight since last report. Health excellent.

SUBPERIOSTEAL SQUAMOMASTOID ABSCESS.

By O. A. LACRONE, M.D.,
OF KALAMAZOO, MICH.

SUBPERIOSTEAL squamomastoid abscess generally occurs as the result of infection of the mastoid antrum and cells, the pus passing between the plate of the squamous portion of the temporal bone which covers the antrum, and the mastoid. The periosteum being more easily separated over the squamous portion than over the mastoid, the swelling occurs above the ear. It is generally an acute process and presents a formidable aspect, as the three cases recently coming under my observation will illustrate.

CASE I.—P., aged fifty-four, consulted me for a swelling above the ear of such size that it pushed the upper part of the ear down and out, until it formed an angle of about forty degress with the head. He stated that two weeks before he had had slight pain in the ear, which had soon subsided, but the noises in the ear had caused him considerable uneasiness, and for one or two days he had been suffering intense pain above the ear and in the eye of the affected side.

I could not discover pus or inflammatory action in the middle ear, and the drum was not even congested. I directed hot applications, leeches, and an anodyne for the night, and in the morning found him resting comfortably. He had no pain, the temperature was normal, and there was but slight tenderness on pressure. I ordered the hot applications continued, but in a few hours was summoned and found the patient suffering intensely and considerably alarmed. I made a free incision down to the bone at the lower and posterior angle of the swelling, at the junction of the squamous and mastoid portions, but could detect no pus. The depletion caused by the free hemorrhage gave him relief, and he rested well until two days later, when the swelling rapidly extended over the mastoid. A second incision was made, a small quantity of pus escaped, and the bone was found to be eroded over part of the squamous and mastoid portion. The wound was cleansed and packed with gauze, and he made an uninterrupted recovery in a few days. The hearing, which had been only slightly impaired, soon returned to normal, and there has been no inconvenience experienced since. There was no history of injury in this case.

CASE II.—Through the kindness of Dr. Rush McNair, I saw J., aged nine, a robust boy, who had suppurative otitis media following scarlet fever. The ear had been discharging freely for some three weeks, when suddenly the temperature rose to 103° F.; pain became very severe in the side of the head and face, and an immense swelling appeared above the ear, extending forward over the zygoma. An incision had been made over the ear through the periosteum, but no pus was found. Chills, vomiting, and an increase of the swelling over the mastoid rapidly supervened. The sanitary conditions of the place were such that we decided to remove the child to the hospital, where, on the following day, we made a free incision over the mastoid and another over the anterior part of the squamous. We found the entire temporal bone, except the tip of the mastoid process, denuded of periosteum. There was free communication through the antrum to the tympanum. A large quantity of dark-colored pus escaped. The wound was thoroughly irrigated with bichlorid solution, and a strip of gauze was passed through both openings. The discharge from the ear soon ceased, the temperature dropped to normal, the appetite returned, and the pain completely subsided.

CASE III.—A well-developed and healthy child, aged nine months, had suffered from pain in the left ear for a short time, which soon subsided, and as there was no discharge from the ear, no further notice was taken of it until two weeks afterward, when a swelling suddenly appeared above and behind the ear. The temperature was 101° F., and pulse 110; the appetite was good, but the child was unable to sleep well, and would not lie on the affected side. I made an incision over the mastoid down to the bone, and a considerable quantity of dark, thick pus escaped. The mastoid and part of the squamous portion of the bone were denuded of periosteum, and the bone eroded and greenish. The abscess was thoroughly washed out and a drainage-tube inserted. After two days the child was removed to its home in Otsego. Three days later the tube had dropped out; there had been no pus since the second day. I washed the wound again thoroughly, and as no pus escaped, I did not again insert the tube. The child made a good recovery, and has since had no trouble.

It will be noticed that in two of the three cases the drum had not been ruptured, and the pain had been so slight that no suspicion of middle-ear trouble was entertained. It is not so strange that this should occur in a child where the plates of bone are connected by a fibrous matrix, and the pus finds easy egress, but it is peculiar to find it in the case of a man fifty-four years of age, even though extensive and destructive inflammation of the middle ear may occur without rupture of the tympanic membrane.

These abscesses are not common, nor are they as dangerous as those affecting the antrum and cells. The acuteness of the attack and the severity of the symptoms demand immediate attention. Mastoid abscess, on the one hand, may be easily overlooked unless the inflammation be severe enough to destroy the mucous lining of the cells and attack the bone beneath. Both varieties present easy roads for the entrance of pathogenic organisms to the brain—the squamomastoid variety through numerous veins which connect directly with the lateral sinus through the mastoid foramen, and the mastoid variety through thrombosis of the veins in the mucous membrane, when the inflammation is severe enough to produce that result, and by erosion and necrosis through the tegmen, antrum, and sigmoid groove.

MEDICAL PROGRESS.

Differential Diagnosis of Abscess of the Brain,—In the *Fortschrit d. Medecin*, November 15, 1896, OPPENHEIM emphasizes the difficulty of differential diagnosis in traumatic brain abscesses, which may be confounded with traumatic meningitis, apoplexy, encephalitis, tumor, epilepsy, traumatic neuroses, etc. Cases cited prove how easily a one-sided traumatic apoplexy, or a hemorrhagic non-purulent encephalitis may, from symptoms alone, be taken for abscess. Oppenheim mentions a striking case in a boy, in which a wound on the forehead was followed by slow pulse, optic neuritis, rigidity of the neck, etc. A diagnosis of frontal abscess was made, but puncture gave no pus. On the following day the pulse was 144, there was fever and unconsciousness, and rapid death. The autopsy showed a well-developed tubercular meningitis. The boy was ill before the accident. The traumatism merely gave an impulse to the development of the disease.

Suppurative meningitis occurring with an abscess is likely to be overlooked. An abscess of the brain is marked by normal or subnormal temperatures; fever is by no means a necessary symptom. If an attack begins with a rise of temperature, it is probably not due to an abscess of the brain—certainly not to an uncomplicated one. A slow pulse is, perhaps, the most reliable single symptom.

It is also well to remember that patients suffering from ear troubles often become hysterical, and that a hasty diagnosis of hysteria, even if the typical symptoms are present, may falsely be made in cerebral abscess of otitic origin.

Pregnancy and Labor After Operative Antefixation of the Uterus.—The frequency with which backward displacements of the uterus occur, and the increasing use of surgical measures to relieve them, give an especial interest to the report of pregnancies occurring after the various operations for antefixation, GRUSDEW has reported in the *Münchner med. woch.*, November 17, 1896, the results in 123 operations of this character. In fifty of the cases a ventral, or vesical, or ventro-vesical fixation was performed; in forty-one, Alexander's operation, and in thirty-two, vaginal fixation. These figures represent only those cases which were kept sight of for some time after operation.

In no case of abdominal fixation did relapse occur. Four of these patients became pregnant, one of them after sixteen years of sterile matrimony. There was no unusual symptom during the pregnancy, except in one instance. In one case, at operation, the uterus was found to be adherent to the inflamed right tube, which was removed. The uterus was then fastened right and left with silkworm-gut to the recti muscles, and with catgut to the vesical peritoneum. Beginning with the second month of pregnancy, there was occasional pain in the right side and straining at micturition. At the end of the fifth month examination by catheter showed the bladder to be situated in the pelvis, underneath the uterus, and extending well to both sides. The urine was perfectly clear. Two of these four cases had normal labors. In the other two, pregnancy was not completed at the time of report.

Alexander's operation was performed upon forty-one women, of whom the subsequent history could be ascertained. It is worth noting that the ligaments were shortened a good deal, in most cases from three to five inches. There was a recurrence of the posterior displacement in three cases, in one of them only after labor. Pregnancy occurred in twenty-three of the patients operated upon, resulting in five miscarriages and eighteen deliveries at term. One of these was with forceps. Several of the patients complained during pregnancy of more or less pain in the operative scars.

Four of the patients treated by vaginal fixation became pregnant. Three of those upon whom Mackenrodt's operation was performed finished the pregnancy normally. In the fourth case the operation recommended by Dührssen, with opening of the peritoneum, had been done. In the second month displacement recurred, and was followed by abortion.

In the light of his experience, Grusdew is inclined to reserve the abdominal fixation for those cases in which there are firm adhesions, or in which disease of the adnexa is suspected, preferring for all uncomplicated cases Alexander's operation. The vaginal operations are less advisable, in his opinion, because the strong attachment of the uterus to the vaginal wall is apt to disturb pregnancy, and if that goes on to term, relapse is not uncommon. Of course, these objections are most potent in young married women.

Antiseptic Properties of Saliva.—HUGENSCHMIDT (*Ann. de l'Inst. Pasteur*, October, 1896) has made an attempt to determine why operations upon the mouth are so seldom followed by infection. He was not able to prove that the saliva possesses any germicidal power. The commoner bacteria grow rapidly in it. Nevertheless, it has a two-fold mechanical action to keep down infection. It dilutes and washes away alimentary material, and by its alkalinity it prevents fermentation.

But Hugenschmidt thinks the saliva possesses the power of stimulating diapedesis in the numerous lymphatic organs situated in the mouth. Even in its normal state the saliva contains products of the secretion of microbes, and therefore possesses an attraction for microbes, and thus favors the phagocytic action.

This hypothesis the writer upholds by several experiments. One of them was the introduction of small glass tubes into the abdomen of the guinea-pig. These tubes were closed at one end and filled with saliva. In eight hours it was found that the leucocytes had crowded into the open end of the tube, forming a plug about two mm. in thickness.

In a second experiment, a small portion of the mucous membrane of the lower jaw of the guinea-pig was resected and its base mangled with a curette. In twenty-four hours the wound was covered with a layer of leucocytes, in the interior of which were found bacteria of various sorts, apparently of the same sorts as those in the saliva. From these, and other experiments. Hugenschmidt concludes that the saliva has no germicidal power, and that the freedom from infection of wounds in the mouth is due to active phagocytosis, brought about by the power of the saliva to stimulate the diapedesis of leucocytes.

Relation of the Sexual Organs to the Skeleton.—HENRY MEIGE in the *Journal des Connaissances Médicales*, 1896, speaks of their regularities in the development of the skeleton often observed among those whose genital organs are atrophied, either from accident or from some congenital cause. One naturally asks the question whether atrophy of the sexual organs does not influence to some degree the development of the bony tissue. It is known that under the influence of some irritating cause the bones undergo malformations, either an enlargement or an atrophy. No one has been able to give a satisfactory explanation of these two contrary conditions. In studying more carefully this question, anomalies of the skeleton are found to occur more often in the case of individuals suffering from atrophy of the genital organs.

In the case of infantilism and effeminacy a congenital atrophy of the sexual organs is nearly always accompanied by some characteristic change in the skeleton. In a general manner, it may be said that in such cases the skeleton holds a place half way between that of man and woman. But on the other hand, under these same conditions one sees sometimes giants, then again dwarfs. The latter, however, seem to predominate, although it cannot be said that an atrophy of the sexual organs is the true cause of this lack of development of the bones, for in these cases there is nearly always an imperfect development of some part of several different organs. In nearly all the cases of an over-development of the bony tissue there is observed a marked atrophy of the sexual organs; this is also noticed in the case of those who have accidentally been castrated; eunuchs, also, often have very large frames. In other cases, anomalies are noticed only in certain bones, or parts of bones. So individuals of an infantile or effeminate type often suffer from *genu valgum*, or from different exostoses, and are especially subject to inflammations of the bony tissue. It is well known that at the age of puberty there is a rapid growth of the skeleton; sometimes this is uniform, sometimes only partial. Over-development of the bony tissue is also noticed in animals that have been castrated, and it is generally the hind legs and buttocks that are increased in size. For example, capons have very long feet; the hoofs and the hindquarters of the ox are more developed than those of the bull. From such facts as these Meige concludes that there must exist some relation between the development of the sexual organs and that of the skeleton.

Treatment of Club Foot.—BILHAUT (*Journal de Médecine de Paris*), in an article on paralytic club foot, calls attention to the fact that deformity of the foot almost always follows paralysis of a lower extremity in a child. This is the case whether the paralysis is due to a myelitis anterior or is spastic in character. For this reason the foot should immediately be secured and supported in a proper position for locomotion.

In neglected cases where the deformity has existed for some time, contractions of the muscles, tendons, and ligaments will have taken place, and the position can be corrected only by operation. In some cases there are marked bony changes also, and operation upon the soft parts is not sufficient, cuneiform osteotomy or removal of the astragalus being necessary to bring the foot into a proper position.

A Simple Method of Abdominal Massage.—STEINHARDT (*Allg. Med. Centr. Ztg.*, No. 70, 1896). A hollow sphere 4 inches in diameter is made of two pieces of hard wood fitted together with a screw. The cavity is partially (not more than $\frac{5}{6}$) filled with buckshot. Immediately before rising in the morning the patient, still fasting, rolls this ball over the abdomen for about fifteen minutes, at first in various directions, and then along the course of the large intestine, from cecum to sigmoid flexure. The falling of the shot within the ball gives a slight vibratory motion which may be increased by lifting the ball until it almost leaves the skin and then dropping it. The treatment is said to cure chronic constipation.

The Outcome of Placenta Previa Cases in Koblenz.—In the *Centralbl. f. Gyn.*, No. 36, 1896, FUTH tabulates the statistics he obtained from midwives in Koblenz with reference to cases of placenta previa occurring in their practice. The material involved 50 mothers and 53 children. A physician was present in 44 of these cases. Of the 50 mothers, 19 (38 per cent.) died, 2 before delivery, 2 during delivery and 15 after delivery. Of these last, 4 died from loss of blood, 6 from septic infection, 4 from the effects of previous hemorrhage, and one from an unknown cause.

Of the 53 children, 32 were born dead and 10 others died in the first 9 days. Only 11 (20.8 per cent.) outlived a month.

In 12 cases (2 of them fatal) the first hemorrhage appeared just before labor pains. In 38 cases between the first hemorrhage and labor there was an interval of days, weeks, or even of months, during which time the physician, or sometimes the midwife, tamponed the vagina.

Füth believes that many of the mothers might have been saved if the physicians had followed the two cardinal principles which ought to govern these cases:

1. As soon as a diagnosis of placenta previa is made labor ought to be induced.

2. Only that form of treatment is advisable which stops the hemorrhage and rapidly dilates the cervix, so that the doctor may be by the bedside until the child is delivered. This is especially necessary in the country, where it may take hours to get a physician.

These ends are best accomplished by an intra-uterine colpeurynter with continued traction upon its tube, followed—as soon as dilatation permits—by podalic version.

THE MEDICAL NEWS.

A WEEKLY JOURNAL
OF MEDICAL SCIENCE.

COMMUNICATIONS are invited from all parts of the world. Original articles contributed *exclusively* to THE MEDICAL NEWS will after publication be liberally paid for (accounts being rendered quarterly), or 250 reprints will be furnished in place of other remuneration. When necessary to elucidate the text, illustrations will be engraved from drawings or photographs furnished by the author. Manuscripts should be typewritten.

Address the Editor : J. RIDDLE GOFFE, M.D.,
No. 111 FIFTH AVENUE (corner of 18th St.), NEW YORK.

Subscription Price, including postage in U. S. and Canada.

PER ANNUM IN ADVANCE	$4.00

SATURDAY, JANUARY 16, 1897.

IS THE COUNTRY DOCTOR A DISTINCT SPECIES?

A NEW poem, uniting praise and pity for the country doctor, has begun to go the rounds of the medical press. Like the old ones, it is quite pathetic and quite good poetry, but is there a true foundation for the sentiment on which these country-doctor poems, orations, and stories are based? And, if not, is there an adequate excuse for writing even good poetry and good prose which will tend to foster false ideas?

We are all familiar with the poetry-country-doctor. He has hayseed in his hair and mud on his boots, his hands are large and calloused, while his heart is big and tender; he rides incredible distances, usually at night, and a very stormy night at that; he is very badly paid—and usually in apples, potatoes, and hay. He is uncouth, and we are informed very distinctly that his advantages have been decidedly lacking, yet his conscientious devotion to his calling and his insight into human nature are such that he accomplishes therapeutic miracles. But, unfortunately, just enough complicated cases are recognized by the poet to bring in a soft-handed and hard-hearted city consultant, who steals the glory and appropriates the possible financial recompense of the unsophisticated country hero. All this sort of poetry creates a sentiment against the city physician and begets a maudlin sympathy for the country doctor—the kind of sympathy that leads to letter-writing, and that would like to express itself in the sending of a barrel of old clothes, but which does not conduce to professional respect nor to professional employment; for it is a characteristic of human nature not to give employment to any one who really needs it, unless that employment is such as sawing wood, or cleaning out a cellar, or sweeping a walk.

Now, speaking as one so bred in city life that existence in the country would be as uncomfortable as the life of a fish out of water, we wish to protest against the sentiment that the country doctor is an essentially different being from the city doctor, and most emphatically that he is any more of a hero and any less of a gentleman than the latter. A man of common sense dresses somewhat differently for a ten-mile drive against a sweeping wind than for a mile-ride through streets whose buildings prevent any prolonged exposure to the wind; he also conforms to the customs and financial habits of the community in which he lives. But, with these provisos, a considerable acquaintance—and an acquaintance on a personal, friendly basis—with country practitioners, has failed to justify the type as depicted in the class of literature referred to.

A study of the graduating class of the average medical school will, we believe, show that the men who are planning for a country practice are just about the same kind of men as those who are expecting to engage in city work. We must also grant that, strictly speaking, there are very few *country* doctors, for the doctor must locate in some business and social center, however small; so that he can scarcely be considered a resident of the country, while he enjoys the privileges of social intercourse with his fellow villagers. The man who seeks a new country, be he physician, lawyer, farmer, or business man, expects to put up with the inconveniences of pioneer life, and can scarcely ask for sympathy on that account. The physician who chooses to locate in a small town in any of the thickly-settled States, has usually ready access by rail to the larger cities, where the advantages of museums, theaters, and other places of amusement, libraries, and large stores may be had without great expense or inconvenience.

While the fees of the country practitioner seem low to his city colleague, his expenses are even proportionally lower. We have been informed that the expense of keeping a horse in the country, or in a small village, is about 10 cents a day—not much more than a tenth of the expense in a large city; the disproportion in rent is approximately as 1:5 or 1:10; household supplies are obtained at slight cost, and many drains on the purse of the city doctor are entirely lacking.

The village doctor, moreover, deals with a comparatively fixed population, most of his clients being responsible property-owners, while the city physician is plagued with a relatively large pauper class and with another class who live better than the average resident of the country or village, but who are absolutely irresponsible for debts. There is no doubt whatever, that the financial trials of the first few years of city practice are practically wanting in the experiences of the country practitioner, and the latter, though perhaps not in the position to look forward to the possibilities of a large income, is much better able to lay up property and to occupy a relatively high position in the society in which he lives. It ought to be rather a matter of individual taste than of economic judgment whether one is to live in a city or in a small village.

Comparisons are always liable to involve odium, and they are especially to be deprecated when they tend to make two classes of what ought to be one body. The man who succeeds in making the Nebraskan believe that he is different from the New Englander has sown the seed of civil war. The belief in a difference is the precursor of enmity. Say to a man that he is not the same as another, and he immediately begins to formulate points of difference. Whenever he finds himself more fortunate, he pities, and, as a natural consequence, despises his rival. Whenever he finds himself less fortunate, he envies, and, as an equally natural consequence, hates. If the poet of the country doctor were inspired by true conditions, it would still be wise for him to refrain from inciting a sentiment that must inevitably tend to schism and mutual distrust. If, as we believe, his verses voice a false conception, they are not only a menace to professional unity, but an insult to both contrasted parties, each of whom is caricatured.

ACROMEGALY AND GIANTISM.

Several most interesting "missing links" between acromegaly and giantism have been supplied of late. On the one hand, Virchow and others have reported cases of marked increase, not merely of bulk, but of muscular strength in acromegalic subjects, followed, however, by rapid decline; and on the other hand, in two almost identical cases giants who were champion "strong men" and wrestlers up to their twenty-second and twenty-fifth years, respectively, after alleged "strains" during feats of strength, broke down and rapidly developed into well-marked cases of acromegaly, with characteristic marasmic symptoms. In the writer's case so much height was lost by the kyphosis and muscular collapse that the poor fellow was no longer available for exhibition purposes, while the attention attracted by the enormous overgrowth of his hands and feet was a source of much mortification to him.

Unfortunately, no light is thrown upon the relations of the two diseases by the results of treatment; nor is much to be expected, for if the dystrophy be due to an excessive pituitary secretion, whether normal or abnormal, but little is to be expected from the addition to the body-fluids of any form of pituitary extract. The negative results from its administration in the few cases in which it has been tried are not in any way surprising.

There appear to be, so far, only two other rays of light upon the problem which can be glimpsed—and they very feeble and remote ones. One comes from the group at the other end of the stature-scale, the dwarfs. Upon attempting to study them, the first fact that presents itself is that the "true" or healthy dwarf is almost as rare as the "true" giant. The study is far from complete, but so far as it has gone, a very large proportion of the cases are obviously due to either tubercular caries and curvature of the spine, hereditary syphilis, cretinism, or rickets. A non-pathologic dwarf is rare, and nearly fifty per cent. of them are rachitic. Furthermore, the "undergrowth" is in precisely the same situations in dwarfs as the overgrowth in giants, *viz.*, the lower limbs, arms, and jaws, the trunk being singularly little affected in proportion, so that their defect is much less noticeable in the sitting posture. Their facial angle is usually large, owing to the small jaw, and their foreheads prominent. Finally, in the two or three cases in which special measurements have been taken, the pituitary fossa is as markedly diminished in size, in proportion to the cranial circumference, as it is increased in the giants, although, in so small a number of cases, this may be a mere coincidence. Still, when the skeletons of an acromegalic giant and a rachitic dwarf are placed side by side, and carefully compared, the conviction rises almost involuntarily that they are actually the opposite extremes of one and the same process. The fact that we have already a definite pathologic condition, or rather name, to account for the latter is no bar to the suggestion, for the causation of rickets is almost as much of a mystery as that of acromegaly. Essentially, it appears to be an ataxic myxedema of the growth-zones of the bones, and has many features which strongly suggest that it also may be due to some disturbance of the internal secretions of the thyro-pituitary group. At all events, the administration of pituitary or thyroid extract in its earlier stages would be a perfectly legitimate experiment, and might lead to some interesting results.

The same narrowing of the pituitary fossa was found in each of three cretinous skulls examined, the fossa in one of them being reduced to a mere transverse slit, and Virchow, in his classic monograph, "Die Entwickelung des Schädelgrundes," gives drawings of two cretin skulls in which the same condition existed. He also speaks of this "sphenoidal kyphosis" as one of the characteristic signs of the cretin skull-base.

A careful survey of the field of comparative medicine has as yet revealed no similar dystrophy in the lower animals, unless it be the singular condition in horses known as osteoporosis, which has passed into popular idiom as the "big-head." As its names imply, the disease is characterized by, first, an extraordinary overgrowth of the jaws and facial bones, rapidly followed by porotic softening and breaking down of the hypertrophied tissues, usually ending in death from general marasmus within a year or eighteen months. It is a disease of young life (second to fourth year), occasionally attacks the bones of the feet and legs, and is in some cases associated with extraordinary precocity. Several members of a celebrated family of imported hackneys, that matured so early that as two-year-olds they swept everything before them in the show-ring, beating even four- and five-year-olds, died in their fourth or fifth year of osteoporosis, literally "falling to pieces under the strain of their own weight," as the attendant veterinarian graphically expressed it. In its localization, course, and results, therefore, the disease presents some show of family likeness to acromegaly. Unfortunately, the pituitary fossa in the horse is an extremely shallow groove, with hardly any definite boundaries, except in front, so that from a careful examination of a number of osteoporotic skulls it was impossible to decide whether the pituitary body had been enlarged or not. One other suggestion of possible bearing upon the problem has been made from a clinical standpoint, and that is whether the extraordinary disturbances of growth and general nutrition in children, associated with adenoids in the vault of the pharynx, "post-nasal growths," may not in some way depend upon the fact that this "pharyngeal tonsil" is, embryonically, simply the lower portion, or stalk, of the pituitary body, from which it has become separated by the ossification of the base of the skull. Not infrequently, in early life, a fibrous cord still runs up through the body of the sphenoid, connecting the two glands, and it is not unreasonable to suppose that structures which were originally continuous may yet retain reflex sympathy with and influence upon each other's condition. All who have studied the condition are agreed that the obstruction to respiration or other mechanical effects of these growths are utterly inadequate to account for the tremendous disturbances of nutrition, both bodily and mental, associated with them and relieved by their removal; and their "pituitary reflex" action has been suggested by no less an anatomical authority than Harrison Allen and endorsed by Osler and Dana.

One of the most convincing collateral proofs of the importance of the pituitary is to be found in its fascinating development and ancestral history, but into this the lack of space forbids us to enter. Suffice it to say that it is now regarded as the remains of, first, the primitive gullet, round which the entire brain was developed, and secondly, of a canal which connected the alimentary tube with the central canal of the nervous system. As the brilliant researches of Andriezen have shown, this canal is still open and functional in larval forms of Ascidians and Amphioxus, and a glandular mass is developing in its wall whose secretion exercises an important influence upon the nutrition of the nervous system. So conclusive were the results obtained by him that he actually ventured to predict the symptoms which would follow the destruction of the pituitary in mammals. About a year afterward experiments made by other investigators upon kittens resulted in the production of no less than four out of the five symptoms predicted by him.

From all which considerations, we venture to tentatively conclude:

First: That the pituitary body is still functional.

Second: That disturbances of its metabolism are the principal factor in both acromegaly and giantism.

Third: That it is not improbable that a similar factor exists in "dwarfism," rickets, and cretinism.

Fourth: That a reflex disturbance of its function may possibly underlie the dystrophy accompanying pharyngeal adenoids.

Fifth: That it would appear to be a sort of "growth-center" or proportion-regulator of the entire appendicular skeleton.

WOODS HUTCHINSON, M.D.

ECHOES AND NEWS.

The Northern Tri-State Medical Association.—This Association, consisting of representatives from Ohio, Indiana, and Michigan, will hold its next annual meeting at Ft. Wayne, Indiana, January 19, 1897.

Surgeon to the American Yacht Club.—It is reported that Dr. Charles I. Pardee, Dean of the Medical Department of the New York University, will be elected fleet surgeon at the approaching annual meeting of this club.

Cholera Carried to England.—A transport from Calcutta arrived at Plymouth, Eng., last week, and reported that five deaths from cholera had occurred among the soldiers and sailors during the passage. The ship has been quarantined, and other cases are expected.

Professor Chittenden Ill.—The severe illness of Professor Chittenden, who occupies the chair of Physiological Chemistry at the Yale Scientific School, has caused his friends much alarm during the past week. Happily, the latest accounts suggest some improvement in his condition.

New Medical Chief at Randall's Island.—Dr. Edward Kershner, formerly a medical inspector of the United States navy, has been appointed chief of the medical staff on Randall's Island, New York, in place of Dr. E. J. Tucker, recently removed by the Commissioners of Charities.

University of Pennsylvania Statistics.—A table recently issued by the University of Pennsylvania, Philadelphia, shows that the total number of students now in attendance at the University is 2811, of which 968 are in the medical department, and 373 in the department of dentistry. Forty-four states and territories, and thirty-four foreign countries are represented.

Pharmacists in Connecticut.—The State Medical Association of Connecticut has determined to bring a bill before the legislature of that State repealing the feature of the present medical practice act which exempts pharmacists from its provisions. It is asserted that many quacks now evade the law by becoming pharmacists. It will also be suggested that the registration fee for physicians shall be raised from $10 to $25.

The Germ of Yellow Fever Discovered.—A cable dispatch from Rio de Janiero to the *London Times* this week states that a young Italian, Giuseppe Sanarelli, by name, has undoubtedly discovered the yellow fever germ. Sanarelli is the director of the Uruguayan National Institute of Experimental Hygiene, and a follower of Pasteur. He is said to have sent an account of his discovery under seal to the Academy of Medicine at Rome.

The New York Academy of Medicine.—At the annual election, held Thursday, January 7th, 1897, the following officers were chosen: President, Edward G. Janeway, M.D.; vice-president, Everett Herrick, M.D.; trustee, Joseph D. Bryant, M.D.; trustee, to serve three years, Clement Cleveland, M.D.; member of committee on library, Charles H. Knight, M.D.; member of committee on admissions, T. E. Satterthwaite, M.D.

Doctors Strike for Higher Fees.—A strike of doctors at Yarmouth, Eng., has just failed. The physicians in the town demanded higher fees from the benefit associations than had been paid, and a limitation of the classes of patients to be attended at club rates. The associations combined, and finding that they provided $10,000 worth of business a year, established a central office of their own, hiring a doctor from out of town to manage it.

Scarlet Fever Caused by Infected Milk.—A group of cases of scarlet fever at East Orange, N. J., affords corroborative evidence of the theory that epidemics of scarlet fever may be caused by infection derived from the milk supply. Nearly all the victims in this group are grown persons, and the sanitary officers claim to have obtained conclusive proof that the germs were brought to the afflicted families in milk supplied by a man whose helper in the dairy was convalescent from the disease.

Semi-Centennial of the New York Academy of Medicine.—The invitations to the Semi-Centennial Celebration of the Academy, beautifully engraved and entirely worthy of the Academy and the occasion, have been issued. The exercises will consist of addresses by President Cleveland and Dr. Joseph D. Bryant, and an oration by Dr. A. Jacobi, at Carnegie Music Hall, and a reception in the parlors of the Academy, with music and refreshments. A most enjoyable and edifying experience is anticipated by all who attend. The date of the celebration is January 29th.

The Bubonic Plague at Bombay.—The disastrous effects of this scourge, which have been noted from time to time in these columns, seem now to be greater than ever. Since the appearance of the disease Bombay has lost more than 300,000 inhabitants, who have fled to the country districts. The absence of all quarantine restraint makes it altogether probable that the infection has thus been spread over a wide area. In conjunction with the famine now afflicting the Indians their numbers will be seriously reduced by the "Black Death."

Protest of the N. Y. Medico-Surgical Society.—At a stated meeting of the N. Y. Medico-Surgical Society, held on January 4, 1897, the following resolution was unanimously adopted. "*Resolved*, That the President appoint a committee of three to draw up resolutions protesting against the clause in the draft of the charter for the Greater New York, which reads as follows: 'The Health Commissioner, who is not a physician, shall be President of the Board.'" The Committee was further instructed to present said resolutions to the proper authorities.

Aphasia of the Hand.—It may be readily appreciated that when a deaf-mute has lost the power of expression by the ordinary manual alphabet the condition is something more than simple agraphia. Such a case is reported by Professor Grasset of Montpellier, France. A man, who since his childhood, had practised the finger language and employed his right hand almost exclusively, after the occurrence of a cerebral thrombosis, was found to be entirely unable to communicate with this hand either by the sign language or in writing, although the paresis of the member was insufficient to account for his aphasia. With the left hand he still expressed himself without difficulty.

Sir Astley Cooper's Largest Fee.—The largest fee ever received by Sir Astley Cooper was tendered to him in a somewhat original manner. He had been attending in his capacity of surgeon a West Indian millionaire named Hyatt, with Drs. Lettsom and Nelson as physicians. The treatment was most successful, and in his joy Hyatt bestowed 300 guineas on each of the doctors. "But you," exclaimed the grateful patient, addressing Sir Astley, "you shall have something better." With this he flung his nightcap at the eminent operator. "Sir," replied the latter, "I'll pocket the affront." And he slipped the "affront" into his pocket. It contained a draft for 1,000 guineas.

The Interment of Pasteur.—On the 26th of December the impressive ceremonies attending the removal of the remains of Louis Pasteur, from Nôtre Dame to the splendid mausoluem which has been erected as their final resting place, occurred. Such a convocation of men of the highest rank in science has rarely been witnessed. Besides the throng of French delegates many foreign representatives were present. The final ceremony at the crypt consisted of the usual religious rites, and of the consignment of his father's body to the care of the future authorities of the Institute Pasteur by the only son, M. J. B. Pasteur, who is First Secretary of Legation at Madrid. M. Bertrand responded, accepting the trust, and eulogizing the illustrious founder of the Institute. These remarks were followed by short addresses from MM. Ramband, Paul Baudent, and Legouvé. The British delegates, Sir Joseph Lister, Sir Dyce Duckworth, Sir William Priestley, Sir John Evans, and Professor Crookshanks, spoke next. After them, remarks were heard from MM. Cornu, President of the Academy of Science; Bergeron, Perpetual Secretary of the Academy of Medicine; Perrot, Director of the Ecóle Normale; Tessier, President of the Student's Association, and lastly, M. Ducleaux, who paid a feeling tribute to his old and honored master.

Infection by Pets.—A case is narrated in *La Médecine Moderne* of a seamstress who was in the habit of allowing her dog to lick her face. Her right eye was attacked with inflammation which became so severe as to endanger the safety of the left one. Enucleation of the right eye became necessary, and in it was found a tape worm, which the dog had probably picked up while licking some less pleasing object. The danger of the transmission of parasites by dogs in this way, owing to the prevalent custom of allowing dogs to lick the hands and faces of their masters and mistresses, is a great one. The wonder is that accidents similar to the one narrated do not happen oftener than they do.

N. Y. State Medical Society.—The ninety-first annual meeting of this Society will be held at Albany, January 26, 27, and 28, 1897. Provisional Program: Tuesday Morning Session, 9.15 o'clock. President's inaugural address. Reports of officers and committees. Executive business. Papers—1. Two cases of Acute Intestinal Obstruction from Foreign Body, with Operation, Dr. C. Wilmot Townsend, New Brighton. 2. Excision of the Coccyx for Fracture and Necrosis, with a report of three cases, Dr. Edward N. Liell, New York. 3. The Fitting of Glasses, Dr. M. L. Foster, New York. 4. A Contribution to the Study of Cough due to Irritation of the Upper Respiratory Tract, Dr. Chas. N. Cox, Brooklyn. 5. M. Phelps, New York. 7. Rectal Discussion: I. Stricture of the Rectum, its Etiology and Treatment, Dr. Joseph M. Matthews, Louisville, Ky. II. The Surgical Treatment of Cancer of the Rectum, Dr. Daniel Lewis, New York. III. When is Colotomy Justifiable, Dr. Charles B. Kelsey, New York. IV. The Proper Method of Treating Internal Hemorrhoids, Dr. Robert T. Morris, New York. V. Preventive, Operative, and after Treatment of Fistula in Ano, Dr. Edward Clark, Buffalo. VI. Prolapse of the Rectum, Dr. George R. Fowler, Brooklyn.

Wednesday Evening Session in the Senate Chamber, 7.45 o'clock. Anniversary Address by the President. Annual dinner at the Kenmore Hotel, 9.30 o'clock.

Thursday Morning Session, 9.30 o'clock. Report of the Committee on Nominations. Papers.—1. The Importance of Choked Disk (optic neuritis) as a Symptom of Brain Tumor, Dr. Wm. C. Krauss, Buffalo. 2. Notes of Cases in Suggestive Therapeutics (hypnotism), Dr. H. S. Drayton, New York. 3. The Comparative Value of Optometric Methods, Dr. C. M. Culver, Albany. 4. Deficient Excretion from Kidneys, not originally diseased, and some Diseases Peculiar to Women, and Diseases of the Skin, Dr. L. Duncan Bulkley, New York. 5. The Necessity of new Methods of early Diagnosis in Tubercular Disease to Curative Treatment, Dr. J. B. Ransom, Dannemora. 6. A Rare Complication of Acute Rheumatism, Dr. Eugene Beach, Gloversville. 7. A Case of Hernia of a Sarcomatous Ovary, Dr. George Seymour, Utica.

CORRESPONDENCE.

INTRAVENOUS SALINE INJECTIONS.

To the Editor of THE MEDICAL NEWS.

DEAR DOCTOR: I was interested in reading the article in your issue of December 19, 1896, by Dr. L. A. Stimson, on intravenous saline injections in shock and in septic conditions. In sudden loss of blood, the increase of intra-arterial pressure by the injection is, of itself, important, and has been the means of saving life. In septic conditions, its use is new; but if, by osmosis, or by supplying certain needed elements to the blood, it enables the system to rally against the infection and to aid in overcoming it, it is worthy of extended trial. If food can be safely combined with the saline infusion, then it is worthy of a fair trial and the fullest investigation.

One experience has convinced me of its safety: Mrs. M., aged forty-five, married and mother of grown children, had been ill several months in the winter and spring of 1895 with some pelvic inflammatory trouble, which proved to be tubal gestation. She was confined to bed at intervals. In April she grew worse, and septic symptoms became manifest. About the middle of May, I was called in consultation with others. The patient was now in a serious septic condition, with small, but decided, tumor at the site of the left ovary and tube. During the previous twenty-four hours she had had two severe hemorrhages with pus, from bowel, which, without doubt, had come from rupture of abscess into rectum. For thirty-six hours, gradual but deepening coma was manifest. Though the condition was desperate, in consultation it was deemed best to operate at once. Under ether anesthesia, I opened the abscess through the abdomen, adhesions protecting the general peritoneal cavity. Blood clots and débris of tubal gestation were quickly turned out, and the cavity irrigated and drained with antiseptic gauze, the operation being done in a few minutes. The condition of the patient did not justify the hope that she would live an hour.

While using other means, I had the little transfusion apparatus of Jennings and a sterilized saline infusion in readiness. There was also a pint of peptonized milk at hand; so I determined to mix the two solutions, in equal parts, and inject through the median basilic vein. Peptonization of milk (which had been prepared by a capable nurse) would prevent its coagulation. The milk and ordinary saline infusion for transfusion were mixed and strained. I immediately opened the vein, and, with the assistance of the attending physician, injected a quart slowly, at a temperature of about 100°. The coma slightly improved, but only temporarily; but the pulse, which was 160, did improve quickly and decidedly in volume and beats, dropping to 130, with an improved tone. This condition was very well maintained, but after a few hours gradually declined. About five hours from the first injection, the same quantity of saline and milk was injected through the same vein, with same manifest improvement in the circulation. But the coma gradually deepened, the circulation, after several hours, again failing, with no improvement in other respects. The case was regarded as hopeless, and the injection was not repeated. The patient died twenty hours after the operation. The profound exhaustion from sepsis really caused death. Though the fatal result was aided by hemorrhage and shock, these, I believe, did not determine it. Though I had not heard before of milk being used in this manner, I believe its effect was good and the transfusion undoubtedly prolonged life. I should use it again, under similar circumstances, and believe it indicated in shock and loss of blood, and worthy of impartial trial in certain septic cases, even though much less profound than the one embodied in this report.

The use of warm saline infusions in the peritoneal cavity during some laparotomies, to prevent as well as to relieve shock, is known to surgeons. The application of the saline solution to the large peritoneal surface, by its absorption, and probably by the heat to the large nerve ganglia, is of greatest benefit; yet, in some of the more urgent cases, the good effect, I believe, would be more quickly manifested by its intravenous use, and, if support is needed, by the addition of carefully prepared peptonized milk.

In Case V, Stimson, patient suffering from general peritonitis due to perforative appendicitis, life, it is stated, was prolonged three days after operation by intravenous saline injections, when the patient died from intestinal paralysis.

It is of the latter I wish to speak, by reference to the following similar case: On January 27, 1894, I operated on Mrs. W. for gangrenous appendicitis, gas and pus having by perforation escaped into the peritoneal cavity, inducing general peritonitis. On the fourth day after, while progressing satisfactorily from the operation, a laxative having previously been given without effect, intestinal paralysis was painfully manifest. The patient was vomiting frequently and copiously, dark, liquid, fecal matter, which was very offensive. No medicine except the laxative had been given. Speedy dissolution was inevitable, unless the bowels could be moved. Enemas and cathartics are useless in these cases, so I aspirated the transverse colon, without ether, removing a large quantity of liquid fecal matter and gas. Vomiting at once ceased. The bowels moved naturally eighteen hours later, and the patient progressed to a safe recovery, which was due, undoubtedly, to the aspiration.

This condition of the intestines is due to sepsis, aided and aggravated, in many cases, by distention from gas and fecal matter. Medicines are generally useless. The bowels have been incised for relief. Aspiration should be tried in preference to other operative means, because simple and usually devoid of shock and danger, while ether and a more elaborate operation must add to the gravity of the situation. Respectfully,

W. W. Grant, M.D.

Denver, Col., January 9, 1897.

OUR PHILADELPHIA LETTER.

[From our Special Correspondent.]

STATUE TO DR. SAMUEL D. GROSS—ELECTION OF OFFICERS OF THE COLLEGE OF PHYSICIANS—MEETINGS OF THE OBSTETRICAL SOCIETY AND OF THE SECTION OF GENERAL SURGERY OF THE COLLEGE OF PHYSICIANS—LECTURE ON TYPHOID FEVER BY DR. J. C. WILSON, AT JEFFERSON MATERNITY HOSPITAL—AID FOR A PAY HOSPITAL FOR CONTAGIOUS DISEASES.

January 9, 1897.

It is expected that the bronze statue of Dr. Samuel D. Gross, by A. Stirling Calder, recently cast in Paris, will arrive in this country during the present month, and will be erected near the Army Medical Museum in the grounds of the Smithsonian Institute at Washington. The movement for the erection of a statue to Dr. Gross was begun by the American Surgical Association, of which he was founder and first president. With the coöperation of the alumni of Jefferson Medical College, and other warm personal and professional friends, the necessary funds were collected. Congress appropriated a sum sufficient for the erection of a suitable pedestal, and the monument is to be unveiled by a granddaughter of Dr. Gross during the next Congress of Physicians and Surgeons in Washington. This statue is the second of its kind erected in this country to a physician. The other, in New York, being to

Dr. J. Marion Sims, a personal friend and contemporary of Dr. Gross.

At the annual meeting of the College of Physicians, held on January 6th, Dr. J. M. Da Costa announced the death of Dr. Theodore G. Wormley and Dr. William H. Pancoast, and paid a feeling tribute to the memory of these widely-known physicians. Dr. J. M. Anders read a memoir of Dr. H. Ernest Goodman, who died last February. The following officers were elected for the ensuing year: President, Dr. J. M. Da Costa; vice-president, Dr. John Ashhurst, Jr.; censors, Drs. Alfred Stillé, William F. Norris, R. A. Cleeman, and A. V. Meigs; secretary, Dr. Thomas R, Neilson; treasurer, Dr. Henry M. Fisher; honorary librarian, Dr. Frederick P. Henry; member of the council, Dr. G. E. de Schweinitz; committee of publication, Drs. G. G. Davis, D. T. Lainé, and Thompson S. Westcott: library committee, Drs. G. C. Harlan, F. X. Dercum, Charles A. Oliver, Wm. J. Taylor, and C. B. Penrose; committee on Mütter Museum, Drs. John H. Brinton, Harrison Allen, and George B. McClellan; hall committee, Drs. J. Ewing Mears, Morris J. Lewis, W. B. Hopkins, John K. Mitchell, and Casper Morris; committee on Directory for Nurses, Drs. Wharton Sinkler, J. C. Wilson, and J. V. Ingham.

Before the Obstetrical Society at its last meeting, Dr. Charles P. Noble presented "A Contribution to the Technic of Operation for the Cure of Laceration of the Pelvic Floor in Women," and Dr. Richard C. Norris read "A Clinical Report of a Year's Work at the Preston Retreat."

At the meeting of the Section of General Surgery of the College of Physicians, held January 8th, Dr. Charles H. Frazier read a paper on "An Operation for the Removal of a Myxofibroma of the Root of the Neck." Dr. Thomas S. K. Morton gave an interesting talk on "Fractured Ribs in the Aged." Dr. John B. Roberts thought that the interposition of a strand of muscle or periosteum between the ends of the fractured bone might be a possible cause of the frequency of ununited fracture of the humerus. Dr. Alfred C. Wood exhibited a patient from whom he had removed gouty deposits connected with the extensor tendons of the fingers and the anterior aspect of each knee, amounting to nearly a pint.

Dr. W. W. Keene was elected chairman of the Section for the ensuing year.

In the course of lectures which is being given at Jefferson Maternity Hospital, Dr. James C. Wilson had as his subject yesterday, "The Prevention and Care of Typhoid Fever, with Details of the Cold Bath Treatment." The statistics of the German Hospital, where Brand's treatment has been in use, up to January 1, 1896, showed that out of 524 cases treated there 38 had died, a percentage of mortality of but 7.25.

A concert, progressive euchre, and dance was given Wednesday evening at the Academy of Fine Arts, under the auspices of the joint committee of the Woman's Health Protective Association and the County Medical Society, in aid of the building fund for a pay hospital for contagious diseases. About 800 persons were present.

Paris.

THE ETIOLOGY OF APPENDICITIS—TREATMENT OF PRIMARY CANCER OF THE LIVER—EXPERIMENTS IN PULMONARY SURGERY ON DOGS—VALVULAR RUPTURE IN A CYCLIST—PLEURISY WITH EFFUSION DIAGNOSED BY MEANS OF THE ROENTGEN RAY.

Gautier reported before the Academy of Medicine, December 8, 1896, that two patients, a man and a child, who had used milk from tin cans were seized with colic, cramps, etc. It was assumed that they had been poisoned by lead in the milk, as the tinning in the can contained lead. But there is no possibility of milk taking up lead, except under certain conditions, as, for instance, on souring. There was no evidence that the milk was sour, and it was not analyzed. The symptoms were, in all probability, those of intoxication from bacterial fermentation in the milk, resulting from uncleanliness.

In the Surgical Society, session of December 2, 1896, **Brun** combated the theory advanced by Dieulafoy that appendicitis results from the closing of the cavity of the appendix. He had seen cases in which the appendix had been transformed into an absolutely closed cavity without the slightest symptom of septic appendicitis. Further, a number of cases are on record in which, at an operation for the relief of peritonitis of appendicular origin, the appendix was found normal in size, without stenosis or phenomena of retention. Moreover, in appendicitis, the lesions are not always localized in the appendix. The affection frequently appears in children who have previously suffered from enteritis or enterocolitis, and this more general inflammation may even exist after the appendix has been resected.

Walther quoted several cases in which appendicitis supervened in the course of acute and chronic enterocolitis.

Jalaguier held that, in the immense majority of cases, obstruction of the appendix was the result, not the cause, of appendicitis, and that this affection was merely an inflammatory one, usually supervening in the course of general infection of the digestive tract.

The discussion of this question was continued December 9th, when **Broca** said that he had seen several cases with generalized peritonitis which began in an appendix thoroughly permeable.

Tuffier endorsed the opinion already expressed that appendicitis was merely a localization of enteritis. The shape and structure of this organ were exceptionally favorable for perforation. He desired to call attention to a neglected side of this question, namely, intestinal obstruction consecutive to appendicitis.

Segond discussed the *diagnosis and surgical treatment of primary cancer of the liver.* Only twelve cases of resection of the liver for malignant tumors (nine carcinomata, three sarcomata) have been recorded. In all of these cases the operation was successful. A woman from whom he had removed a large fibrocystic tumor of the liver died in twenty-four hours from operative shock. The tumor, which was a trabecular epithelioma with polymorphous cells, sprang from the lower surface of the liver by pedicle. As in most of the recorded cases, the pedicle in this case was treated extraperitoneally.

TERRIER said that the tendency at present, especially in Russia, was to use ligatures placed on the base of the tumor, so as to avoid an external pedicle.

BROCA reported an esophagotomy on an infant six months of age, for the purpose of removing a metal brooch which the child had swallowed a fortnight before, and which could not be felt by a sound previous to operation. The surgical procedure was entirely successful. The diagnosis in such cases is very difficult.

QUÉNU made a brief statement of the results obtained in sixty *experiments in pulmonary surgery on dogs.* All animals in which the pleura was freely opened presented symptoms of dyspnea, and twelve out of fifteen died asphyxiated. It was thus shown that free opening of the pleural cavity is a serious matter when the pleura is healthy. If the visceral pleura was kept in contact with the chest wall, either by suture or by the use of intrapulmonary pressure, its cavity could be opened without danger. The latter condition was accomplished by causing the dogs to breathe compressed air. The results by this method were so favorable that Quénu unhesitatingly recommended it in operations upon the human thorax. Other investigators have shown that this intrabronchial pressure, if it does not go beyond the limits of the elasticity of the lungs, *i. e.*, beyond what is necessary for preventing pneumothorax, is absolutely harmless; and that it does not interfere with the circulation in the lungs, and has little influence on the general circulation.

In the Medical Society of the Hospitals, at the meeting of December 4, 1896, **LAUNOIS** presented a case of *aortic regurgitation due to valvular rupture in a cyclist.* The patient was a man, aged thirty-eight, with no history of rheumatism, or infectious disease, or syphilis, but who had been since 1882 an enthusiastic cyclist, and afterward a well-known long-distance rider. Functional disorder, due to the aortic regurgitation, was remarkably slight.

MENETRIER reported a case of typhoid fever complicated by pleurisy, the interest of which lay in the fact that the pleural serous effusion exerted no agglomerating action on Eberth's bacillus. **WIDAL** and **SICARD** had found an agglomerating reaction in the pleural effusion withdrawn at the autopsy of three typhoid fever patients. If a pleural effusion formed rapidly, this reaction might be absent. Thus, it is present in the normal tears of a typhoid fever patient, but is absent in tears copiously produced by the inhalation of ammonia.

In the session of the Biological Society, held December 5, 1896, **MAYET** reported the results of investigations to determine the *effect of intravenous injections of salt solutions on the red blood-corpuscles.* He found that a solution of sodium chlorid 6–1000 not only did not change the form of the corpuscles, but also did not affect their elasticity. He objected to the addition of sodium sulphate to the solution. The best method of injection is not to denude the vein, but simply to introduce a small hollow needle into a vein which has been distended by a ligature about the limb.

MOTZ examined microscopically thirty hypertrophied prostate glands. In nineteen (or 66.4 per cent.) the glandular tissue was abundant; in ten (33.3 per cent.) this tissue was rare; in one it had completely disappeared. Arterio sclerosis is never found in a prostate in which the glandular tissue occupies two-thirds or more of the section, and this sclerosis is rare even when there is an equal amount of glandular tissue and stroma. It is therefore improbable that arterio sclerosis is the principal cause of hypertrophy of this organ.

At the meeting of the Academy of Sciences held December 7, 1896, **BOUCHARD** discussed the value of the *Röntgen ray in the diagnosis of pleurisy.* In three patients he had found that the area corresponding to the effusion was occupied by a dark tint in sharp contrast with the light color of the healthy side. This method of diagnosis is not any more certain or satisfactory than the procedures usually employed at present, but it has a great advantage in that it is thus possible to demonstrate to an entire audience the existence, extent, and depth of an effusion which otherwise could only be made out by a personal examination of the patient. Bouchard believes that an examination by means of the Röntgen ray will be found as useful in medicine as in surgery.

Vienna.

PROGRESS OF CREMATION — SUCCESSFUL REMOVAL FROM THE ESOPHAGUS OF A FOREIGN BODY CAUSING SERIOUS HEMORRHAGE — THE VALUE OF A BLOOD COUNT IN CANCER.

ENGERTH read an exhaustive and interesting paper on *cremation* before the Society of Physicians, November 27, 1896. As carried out according to the best methods, the body is placed in an iron receptacle the walls of which are brought to a white heat. Upon the introduction of air raised to about 1000° C., the body is ignited and burns in its own flame. Such a cremating oven costs from $1500 to $2000. The cremation of a single body costs from $2 to $3, but if several are cremated one after another the expense is reduced to about 50 cents apiece, so that the financial as well as the hygienic gain to the inhabitants of large cities is very great. It is interesting to notice that the chemical changes produced by cremation in two hours are almost the same as those produced during fifteen years by burial. Among the Christian nations there were in 1894, 110 cremation societies with 37,000 members, and 53 crematories, 23 of which were in Italy, and 18 in America.

At the session of December 4, 1896, **HOCHENEGG** presented a patient upon whom he had operated for a *foreign body lodged in the esophagus.* The hasty swallowing of large mouthfuls of food gave rise to intense pain. As no foreign body could be detected by the sound it was inferred that the esophagus had been lacerated. The symptoms continued, and later there were several serious hematemeses, and a swelling developed in the left side of the neck below the thyroid. At operation this swelling was found to be due to an abscess set up by a piece of chicken-bone which had pierced the esophageal wall. The ulceration had eroded the wall of a dilated vein and so caused the hemorrhage. Hemorrhage from a foreign body in the esophagus is of rare occurrence. In 180 cases it was met with only ten times. In all of these it appeared after the sixth day, and was therefore secondary to ulceration. Of these ten cases only one was saved. The author spoke of the uncertainty of the results obtained by sounding the esophagus and of the value of the esophagoscope in making an early diagnosis.

At the session of the Medical Club held November 25, 1896, BERDACH showed a fifteen-year-old boy who some days before had fallen upon his right shoulder. He could not move the right arm after the accident. The contour of the shoulder was much flattened, but examination showed that there was no dislocation or fracture. Passive motions were free in every direction. The case was one of paralysis, and the interesting question in connection with it was whether it was caused by the accident or had previously existed. The boy had had scarlet fever and diphtheria, but as the paralyses from these are always bilateral and only temporary, they need not be further considered. Careful questioning elicited the information that for some time the right arm had been weaker than the left, and could not be raised above the shoulder. The case was undoubtedly one of acute anterior poliomyelitis, and is interesting as showing how the trauma had suddenly completed the paralysis.

In a discussion on the *practical results of the examination of the blood*, LIMBECK spoke of the great increase in white blood corpuscles which frequently occurs in cases of medullary sarcoma and lympho-sarcoma. The resemblance between the blood in these conditions and in leucemia is very great, so that a differential diagnosis is not easily made. The increase of white blood corpuscles in sarcoma is really due to the existence and growth of the tumor, and disappears with the removal of the new growth. Upon this circumstance rests the significance of the examination of the blood in sarcoma. Some years since, the left leg of a man who had a medullary sarcoma of the tibia was amputated through the knee-joint. It was desirable to know whether or not there were metastases remaining. The high leucocytosis fell after the operation, and was no greater than could be accounted for by the wound. Some weeks later there was a marked increase of white blood corpuscles, although neither in the cicatrix nor elsewhere could a new growth be found. The patient failed and died, and the autopsy showed multiple sarcomata in the lungs.

SOCIETY PROCEEDINGS.

PHILADELPHIA COUNTY MEDICAL SOCIETY.

Stated Meeting, November 11, 1896.

The President, DR. J. C. WILSON, in the chair.

J. T. RUGH, M.D., read a paper entitled

EIGHT PRIMARY MOVEMENTS OF THE NORMAL SPINE AS A BASIS FOR THE GYMNASTIC TREATMENT OF SCOLIOSIS AND ALLIED CONDITIONS.

These movements consist in (1) bending forward, (2) bending backward, (3) bending to the right, (4) bending to the left, (5) combining these movements in circumduction to the right, (6) combining these movements in circumduction to the left, (7) rotation of the spine upon its vertical axis to the right, (8) rotation of the spine upon its vertical axis to the left. This nomenclature is in accord with that of anatomists, who describe the normal movements of joints as flexion, extension, adduction, abduction, circumduction, and rotation. Other movements of which a joint is capable are but modifications of these. In all cases of scoliosis there is more or less rigidity of the spine as a result, not of inflammatory or other pathologic condition of the bony or muscular structures, but of the muscular debility, inactivity, and atrophy, and of the long continuance of the malposture. With this rigidity there is also limitation of movement in one or more directions. The exact degree of such rigidity and limited motion can be ascertained by having the patient perform the primary movements mentioned and noting the degree of flexibility of the spine. The guide to the gymnastic treatment is thus obtained, and exercises that will increase the motion in the desired directions can be prescribed. As all movements are limited to the eight cardinal forms, variety can be had only by change of position. By this means total correction of the deformity in some and partial correction in all may be effected. While certain movements are indicated in certain cases, they are contraindicated in others. The relation that the arms and legs bear to the spine are most important as altering the contour of the latter. If the arm is raised or extended, the spine assumes a curve toward the corresponding side. The same result follows movements of the legs in consequence of tilting of the pelvis upon change in the relative lengths of the legs by lifting or moving one of them in any direction. In this way a lumbar curve may be obliterated; or a dorsal curve, by properly adjusting the arms. By a combination of these two the "key-note" positions, or those in which the greatest amount of correction is secured, are assumed, with a better result in treatment. For the purpose of multiplying exercises, all those positions may be assumed that to a greater or less extent obliterate the existing deformity, such as lying prone or supine upon the floor or a table; sitting on the floor, on a chair, or on a stool, with the legs in various positions, or one hip raised; standing with the feet together, the feet separated, one advanced or retracted; standing on one foot; using the rings, trapeze, or bars; kneeling on one or both knees; squatting, and so on.

DR. H. C. WOOD introduced Mr. Lewis A. Tallerman of London, who demonstrated the Tallerman-Sheffield patent local and medical dry-air bath, and showed the method of its application in the cases of two patients from the Philadelphia Hospital, one suffering from saturnine gout, and the other from lumbago. Both were very materially helped, the patient with lumbago, after having suffered so severely as to require aid to get about, and then only with great pain, being able subsequently to the treatment to walk with ease and comfort. The temperature rose about a degree in forty minutes and the pulse increased nine beats in frequency, gaining also in fulness. The temperature within the apparatus was 260° F., and the pelvis was inclosed for forty minutes. The patient with saturnine gout was able to move joints that had not been moved for a long period of time, and not only those exposed directly to the influence of the apparatus, but also those at a distance and not treated directly. After an exposure of fifteen minutes the man was able to move the worst toe, while the pulse increased twenty beats in frequency, and the temperature had risen 1.4°. The temperature within the cylinder was kept at 260° F. for three minutes; it was then reduced to 255°. Most of the time it was 248°. The apparatus consists essentially of a hollow cylinder surrounded with asbestos, and capable of being closed at either end. The interior of the cylinder, wherein the part to be treated is placed, can be heated by gas to temperatures of 260° and more. Provision is made for the escape of moisture, as well, of course, as for the regulation of the temperature, so that the heat is always practically dry, and thus more tolerable than if it were moist.

MR. TALLERMAN said that among the therapeutic effects of his apparatus are an enormous increase in the activity of the circulation, profuse perspiration of the whole of the body, relaxation of the parts, dilatation of the vessels, and an increase in the bodily temperature of from 1½° to 4° F., with a return to the normal in from fifteen to twenty minutes. In rheumatic affections, rheumatoid arthritis, gout, lumbago, sciatica, sprains, and kindred disorders, pain is relieved or entirely removed. The first treatment is usually followed by relief of pain and freedom of movement. The progress of the disease appears to be arrested and a curative process to be set up. The benefit is not confined to the parts exposed to treatment within the apparatus, but extends to remote parts not directly subjected to the heat. The procedure is entirely painless and rather soothing in its effects, patients manifesting a tendency to sleep during its operation. In chronic cases, when the joints are rigidly fixed by firm adhesions, it has proved wise to treat the limb for a short time in a preparatory way before more active interference is undertaken, and then to break down the adhesions under an anesthetic. If the member is then treated again as soon as the effects of the anesthetic have begun to pass off, the heat exerts an anodyne influence, and the pain subsides in a short time. The apparatus has been employed for several years in a number of large London hospitals, with generally advantageous results.

In answer to inquiries, Mr. Tallerman stated that probably several applications of the treatment would be necessary to insure permanent improvement in cases like those exhibited. To avoid ill effects as a consequence of the treatment, the patients should be briskly rubbed down afterward with a coarse towel. In cases of rheumatoid arthritis, the treatment could be employed four or five times a week at first, and subsequently with less frequency.

There is a special apparatus for the pelvis and for the hand, in addition to that for the leg.

MAX J. STERN, M.D., presented a communication entitled

REPORT OF WORK WITH RÖNTGEN RAYS AT THE POLYCLINIC HOSPITAL, WITH EXHIBIT OF SKIAGRAPHS.

The work was carried out in a large, airy room, darkened, in order that the amount and color of the light in the tubes might be better observed, and because the retina, accustomed to the surrounding darkness, is much more sensitive to an appreciation of the value of an image on the fluorescent screen. The deeper the green light in a tube, and the greater its coincident intensity, the more X-rays are being given off. When the light approaches a yellow color, the visual or fluoroscopic picture is usually better, but the radiographic effect poorer. A chlorid-accumulator storage-battery constituted the source of electricity, while the Ruhmkorff-coil has a spark of eight inches and the regulation spring-vinrator. The Crookes' tubes used are the three-electrode tubes devised by Professor Stein of the University of Chicago. The stand for supporting the tube, as well as all the wires employed, is insulated as perfectly as possible. The subject is placed in a position most favorable for either visual observation or exposure to a plate, as the case may be. The radiographic plate is placed in as close relations with the structures to be delineated as possible. The plate used is one that has been specially prepared for the purpose. The view was expressed that the best plate for the purpose has not been produced, and the suggestion was made that some fluorescent material might be embodied in the emulsion, that by its absorption of, or agitation by, the rays would greatly enhance the activity of the chemic changes in the silver-salts employed. The plates are kept light-proof by packing them separately, first in needle-paper, then in a black envelope, and finally in an outer sealed one of yellow post-office paper. The fluorescope is used to determine the effectiveness with which the tube is acting. In the preparation of skiagraphs it has been found that the more intimate the contact between the sensitized plates and bone, the shorter the exposure required, the less the distortion produced, and the sharper the definition of the resulting picture. On the other hand, the tube must not be held too close to the part to be reproduced, else the picture will be distorted and lack sharpness of definition, and the tissues of the subject may be burned, in degree and severity in accordance with the duration of the exposure and the amount of surface involved. Experience will soon teach the best point at which the tube shall be placed. The necessary exposure will be shorter (1) as the spark is larger, up to a certain point, probably about ten or twelve inches; (2) the more nearly the vacuum of the tube is at the point of exhaustion at which the coil employed will give off the greatest amount of X-rays; (3) the nearer the tube to the proper focal point; (4) the less the density and volume of the tissues in the part to be portrayed; (5) the more sensitive the plate. In printing from the plates, highly glazed papers will yield better results than will most surface-papers. More or less of the detail will be lost in the latter; yet for exhibition-purposes they are better, as the reflection of light from their surface is less, and they can be more readily demonstrated to large assemblies. Any of the good albumin or collodion papers of glossy surface may be used. Much of the beauty of a finished picture is due to the treatment of the plate, and to attain the best results one should first have served an apprenticeship with a practical photographer. While the exposure of a member is under ordinary circumstances unattended with any general disturbance, exposure of the chest is usually followed by acceleration of the action of the heart and alteration in the character of the beat.

DR. ARTHUR W. GOODSPEED called attention to a new and improved tube that he has been using successfully. This is smaller than the tube in common use, and has the quality of maintaining its exhaustion. To accomplish this latter object, some tubes are provided with a third electrode. The new tube referred to is coated with some fluorescent substance which seems to take up on its surface a certain amount of air set free by the action taking place within the tube. If the action is too great, the tendency to raise the exhaustion is counteracted by the setting-free of the gas spoken of; so that, to a certain degree, the exhaustion of the tube may be maintained. If, however, such a tube be worked too roughly—that is, at too high an electromotor-force—the exhaustion is likely to run down. This danger may be overcome by permitting the tube to rest awhile. Dr. Goodspeed has not been in the habit of holding the tube close to the body, and he has seen no bad effects upon the skin. This action may lend support to one of the several theories concerning the ultimate nature of the X-rays. One of these makes the X-rays of the nature of light of very short wave-lengths. Another considers the rays made up of material particles shot off from the exterior of the tube by the bombardment of particles within the tube, these passing through the fleshy material of the subject and producing their impress upon the plate.

MR. JOHN CARBUTT said a great deal of the success in skiagraphy depends upon the development of the plates. The plates from which most of the pictures exhibited were made, were treated with an emulsion containing a fluorescent substance, which causes absorption of the X-rays. Some of the earlier pictures made with ordinary plates were feeble because of the protracted exposure, as, for instance, for an hour or more. Good pictures can be secured in from four to seven seconds, although the average exposure for the hand is from two to three minutes, and correspondingly longer periods for thicker parts of the body. Cathodal rays of a greenish-yellow are best for observation with the fluoroscope, while rays of apple-green are best for photographic effect. With plates made especially for skiagraphic purposes, the development should be continued for from six to twenty minutes. By using celluloid films Mr. Carbutt has been able to make six good negatives simultaneously, showing that glass is less pervious to the rays than celluloid. He has under way experiments directed to the discovery of a silver haloid more sensitive to the X-rays than any at present in use. The longer the radiographic plate is exposed to the X-rays, the more dense the result on the margin, while an overexposure in the camera yields only a thin flat image.

In conclusion, DR. STERN spoke of the desirability of having a plate that could be used in emergency-cases when it is desired to secure a negative at once.

REVIEWS.

FUNCTIONAL DISORDERS OF THE NERVOUS SYSTEM IN WOMEN. By T. J. MCGILLICUDDY, A.M., M.D. Illustrated by forty-five wood engravings and two chromo-lithographic plates. New York: William Wood & Co., 1896.

WE can see, firstly, no reason for the writing of this book, and, secondly, none for its publication. All that it contains, except the reports of cases, has appeared over and over again in medical journals and in monographs and text-books on general, nervous, and gynecological diseases. The work is simply a collection of platitudes, so well-known as to require no elaboration, and the writing is without style, force, or diction. As for the various neuroses, they are quite fully considered, but it is impossible to find anything new, either in the way of theory or symptomatology.

The book-making is fair. The chromo-lithographs are poor, and most of the other illustrations convey no impression of what they are intended to represent.

INFANTILE MORTALITY DURING CHILDBIRTH, AND ITS PREVENTION. By A. BROTHERS, B.S., M.D. William Furness Jenks Prize Essay of the College of Physicians of Philadelphia. Philadelphia: P. Blakiston, Son & Co., 1896.

THIS essay is a critical *résumé* of the causes which threaten fetal life previous to birth, during labor, and during the first few hours of extra-uterine life. The author points out historically the changes that have taken place in the prophylaxis and treatment of these cases. The subject is treated in a lucid and logical manner, and although much of the work is a compilation, as it necessarily must be, the author has rendered a good service to the profession in collecting and arranging his material so admirably.

Statistics of infantile mortality are given, embracing those of the Board of Health of New York City, which show that, between the years 1889 and 1892, 16,000 deaths occurred in New York in newly born children or in children less than a month old. The author gives a study of forty-seven *post-mortem* examinations on newly born infants, and regrets that such examinations are not more commonly made when the opportunity is presented.

The "causes of infantile mortality" are next discussed, and are divided according as the blame must be placed upon the mother, the child, or the accoucheur. The divisions of "before labor," "during labor," and "after labor," are further made. The work concludes with a consideration of measures to prevent the unwilling destruction of fetal life, and a discussion of methods of resuscitation, in which a predilection is shown for Sylvester's method. The essayist has a flowing style, and has made a valuable contribution to the scientific books of the year in the well-printed one before us.

RELATION OF DISTURBANCES OF THE ALIMENTARY TRACT TO KIDNEY DISEASE.[1]

BY WILLIAM VISSMAN, A.B., M.D.,
LECTURER ON PATHOLOGY, BACTERIOLOGY, AND CLINICAL MICROSCOPY AT THE NEW YORK POLYCLINIC.

THE experiments of Bouchard show that intravenous injection at one time of a quantity of urea in excess of what would be excreted by an animal in several days, produces no alarming or serious effects. Furthermore, G. Klemperer recommends administration of urea to man as an excellent diuretic, while Bettman reports a number of cases in Erb's clinic, one patient having taken over 600 grams during the course of several days, without any deleterious effects. In fact, he states that the only unpleasant effect noted was a slight diarrhea in several cases. In the light of this testimony it may not be inopportune to look to other substances as the cause of the chain of symptoms which hitherto have been attributed to intoxication with products of animal metabolism when occurring in the course of renal affections.

It is customary to divide the diseases of the kidney into three classes, namely, those affecting the epithelial lining of the tubules, those expending their force upon the interstitial tissues, and, finally, those in which both the epithelial cells and interstitial tissues are affected at the same time. Clinically, these different forms may be, and often are, diagnosed with great accuracy; but anatomical experience has left the writer in much doubt as to there being a distinct line of demarcation between disease of the parenchyma and of the interstitial structures. However, there are innumerable cases where the great force of the anatomical disturbance is spent either on the parenchyma or the interstitial tissue, while the other remains *comparatively*, but not absolutely, unharmed, depending largely on circumstances.

In making a *post-mortem* examination, the similarity between the anatomical changes in the liver and spleen, and those in the kidney is very prominent, and close examination of the blood vessels throughout the body reveals in almost every organ the same type of lesion as is found in the kidney. Furthermore, careful examination of the bodies of patients who have succumbed to renal disease will usually show a very apparent lesion somewhere in the parenchyma of the alimentary tract, if not throughout its greater portion. These anatomical disturbances may vary within extreme limits. Naturally, the function of the organs will be interfered with in proportion to the gravity of these lesions, Patients suffer from disturbances of all sorts due to interference of excretion and secretion. To illustrate the grave symptoms which may be attributable to a very slight lesion in the alimentary tract, it is only necessary to refer to the records of any cholera epidemic in order to find that some of the apparently most healthy individuals of a community have become victims to this disease. When it is considered that cholera spirilla cannot withstand the normal secretion of a healthy stomach, it becomes very probable that these apparently healthy individuals really had some very slight disturbance of the stomach which interfered with its normal functions. Slight disturbances of digestion are very frequently due to causes to which every one is daily exposed, such as fatigue and indiscretion in diet, as partaking of too hot or too cold food and drinks, to say nothing of the chemical combinations of the ingredients of the drinks taken. The consequences of indiscretions of this character are many, depending altogether upon the substances ingested and the persistence with which the habit is continued.

It is naturally not supposed that one should partake of perfectly sterile food, but it is reasonable to expect that food known to contain pathogenic organisms will be rejected by every one. The nonpathogenic organisms, however, are not so absolutely harmless as they are generally supposed to be. No one could ascribe any ill effect to the ingestion of a delicious cupful of bouillon, yet how many could place the bouillon in what is ordinarily called a clean glass, allow it to stand until it becomes sour, and then drink it with impunity? Yet the same changes wrought by the bacteria in the bouillon in the glass may be, and are, produced in the alimentary canal when its physiological function is disturbed. Under this condition, this canal, with its absence of light, presence of moisture and warmth, and with its contents as a medium for the propagation of germs, is an ideal place for growth and proliferation of bacteria and the formation of the products of their metabolism. The effect on the organism of these products of bacterial metabolism differ according to the organism by which they are produced. They may cause certain well-defined diseases, such as diphtheria, cholera, etc., while others may act simply as sedatives or irritants. The effect on the alimentary canal of sedative or irritating products of bacterial metabolism are too well known to require further discussion at this point. The constitutional effect upon animals when these products of metabolism are administered hypodermically is variable, usually those common to infectious diseases; and when large doses are administered the animals die in convulsions. An excellent idea may be obtained by observing children suffering from so-called summer diarrhea. The children show all of the symptoms of uremia, from the mildest to the most severe, including coma and convulsions. Autopsies of these cases show that the little sufferers have a kidney lesion, generally nothing more serious than a cloudy swelling of the parenchyma. However, a thorough cleansing of the bowel, either by high enema or cathartic, has such a mitigating effect on the little victim's suffering as to give almost conclusive proof that the cause of the trouble was the absorption of something from the contents of the alimentary tract.

---

[1] Read before the Medical Society of the County of New York, December 28, 1896.

Numerous bacteria which produce indol flourish in the intestine, and that the products of metabolism of these organisms enter the blood is evidenced by the voiding of indican with the urine of patients having disturbances of digestion. That the indican in the urine emanates from the alimentary tract is shown by the fact that if this canal is thoroughly cleansed, indican disappears from the urine. It is very probable that bacteria also enter the blood from the intestine and are voided with the urine, for Engel[1] in examining the urine of 31 cases of nephritis found bacteria in 29 cases. Among the bacteria found, the most frequent were pus producers, followed by colon, tubercle and typhoid bacilli in the order named. There are reasons for believing that other so-called non-pathogenic organisms also enter the circulation, because they have been found in the urine after the latter had been drawn with a catheter under aseptic precautions. Even though healthy blood serum has a certain power of disinfection, the work of Buchner, the writer, and others has shown that the dead bacteria possess the power of producing aseptic suppuration.

In 1878, Pasteur proved that sterilized (dead) pus-producing organisms, as well as live cultures, produced suppuration. Later, Grawitz, de Bary, *et al.*, proved the same in connection with staphylococcus pyogenes albus, bacillus prodigiosus, and bacillus pyocyaneus, and Buchner did the same for Friedländer's pneumococcus. Buchner[2] was not convinced that the effect produced by the sterilized cultures was not due to the product of metabolism of the organisms, and he therefore made extracts of the following organisms: Staphylococcus pyogenes aureus, cerius flavus, sarcina auranticus, bacillus prodigiosus, Fitzianus, cyanogenus, megaterium, romosus, subtilis, coli communis, acid lactici, anthracis, mallei, Kieler Wassor, proteus vulgaris, vibrio Finkler Prior., and produced an aseptic suppuration with these extracts also.

The writer[1] has found that if sterile cultures of tubercle bacilli were introduced into the ear vein of rabbits, hemorrhages into the renal glomeruli and interstitial tissue followed. Later, the walls of the blood vessels were markedly infiltrated with round cells, which infiltration also extended to the surrounding connective tissue. The same changes as were noted in the blood vessels and interstitial tissue of the kidney, were also noted in the liver and lungs, and later on, when other experiments were made in conjunction with injections of tuberculin, the same changes were noted, but the addition of the tuberculin treatment intensified the action to such a degree that the changes were very much more pronounced. The arteritis was such as to almost obliterate the lumen of the vessels. The tuberculin used was some of the first made and was, therefore, only a filtrate of a concentrated glycerin bouillon culture of tubercle bacilli. For other evidence that products of bacterial metabolism may, and do, produce nephritis, it is only necessary to examine the kidneys of a patient who has succumbed to an infectious disease. Here the character of inflammation will vary from the mildest (cloudy swelling) to the most serious changes. Fürbinger,[2] Roux and Yersin,[3] v. Kahlden,[4] Senator,[5] and others, proved that the toxins of diphtheria administered hypodermically were equally as effective in producing nephritis as the bacilli. A number of non-pathogenic organisms produce substances possessing virulent toxic properties, and these substances are at times produced in the alimentary canal and, when absorbed, produce marked changes in the kidney. These disease processess will vary in severity according to the nature of the toxin and the length of time the organ is exposed to it.

There are a great number of persons who suffer from slight derangements of the alimentary canal without being suspected of illness. They will give a history of going to stool, once, twice, or three times a day; others, once in two or three days, and almost every patient will say he has passed about a normal quantity, but upon being questioned closely he will inform the physician that he never felt completely relieved at any time. Examination will show that these patients are all voiding an abnormal urine which, when introduced under the skin of a lower animal, will be proved to contain irritating poisonous substances.

Most of the patients, also, excrete small quantities of a very highly concentrated and very acid urine, but others show just the reverse; and almost all the urines will be found to contain abnormal quantities of nitrogen compounds, to say nothing of other abnormal constituents, which may be found on chemical and microscopic examination. The probable cause of the sensation of not having completely relieved the lower bowel will be found to be that scybala are lodged in the canal and produce the disturbance, and that these scybala, aside from the disturbance caused merely by their action as foreign bodies, form an ideal nidus for the growth of bacteria and the production of toxins which, when absorbed and then voided in the urine, irritate the kidney, perhaps only very slightly, but when continued for years, as is the case with most persons following sedentary avocations, are very probably the true cause of the large number of kidney and blood vessel lesions among commercial and professional men.

DISCUSSION.

Dr. Satterthwaite remarked that there were a number of interesting relations between affections of the kidneys and those of the gastro-intestinal tract, which had recently come into prominence. He had been much interested in the case of a patient of his, who had come to him recently with a history of nausea, vomiting, and cramps, with dilatation of the stomach, due, it seemed, to pressure downward of a dislocated kidney on the head of the duodenum. There had been no pressure on the common duct. It was one of those rare cases in men that has been described of late years. He believed there was a small class of cases in which the normal contents of the intestines produced general infection of the spleen. In certain ones, he thought that experiments had shown that where the secretion of the pancreatic juice was diminished or prevented, decomposition of the intestinal contents would take place, and sometimes the functions of the kidneys would be seriously interfered with. This was in a measure corroborative of the position taken by Dr. Vissman, that in the sluggish indigestion of old people, the scybalous feces may give rise to renal troubles of an organic character. But to his mind the most interesting point in the discussion hinged on the casual relations between certain enteric diseases and nephritis. And in this connection he called attention to the fact that during the last year Dr. Seibert of this city appeared to have been the first in his locality to show that the enteritis of infants gives rise in some instances to acute nephritis. Judging from his personal knowledge in an institution with which he was connected, this association of diseases was not a frequent one, however; indeed, in half a dozen examinations in infantile enteritis, no implication of the kidneys was found. The difficulty in the way of determining this matter was a serious one. In infants under two years of age it was very difficult to obtain sufficient urine for examination without resorting to artificial means. In this connection he would remind the audience that neither albuminuria nor general edema, which were tolerably common in the enteric diseases of infants, was necessarily indicative of nephritis. Nothing less than a microscopic examination of the urine should be taken as an evidence of such disease.

In reference to the use of the term *auto-infection*, which had come up in the discussion, he objected to it, because it had come to be used as synonymous with a special bacterial invasion of the tissues, while in this instance, certainly, the kidneys were invaded by several if not many kinds of bacteria. And though the *bacillus coli commune*, whose habitat is in the mucus of the normal intestines, has been found in these cases in the kidneys, it had also been found at the same time in the lungs. As a matter of fact, when infection spreads from the inflamed bowels it is quite as apt to reach the lungs, perhaps the brain or meninges, as the kidneys, and it is quite possible that the kidneys may be infected from the bowels through the medium of one or other of these organs. Nor is there any proof that any of these microörganisms in any enteric disease is the cause of the nephritis, directly. There is but one law on the subject and that is Koch's law. The organism supposed to be specific must be found in the diseased tissues; it must be isolated and a pure culture made; finally, this pure culture when inoculated upon a susceptible animal, must produce the disease in question. Now, as in these cases it has not been shown that any given microörganism will answer this test, we must look for the virus either in some product of the bacteria or in some chemical substance apart from bacteria. He would, therefore, substitute for auto-infection the term endogenetic infection. This word is not a new one, but as used it is meant to indicate that the infection of the body proceeds from within the body, but is not necessarily associated with a given bacterial organism.

But there is also a more practical side to this matter. It is this: In treating enteric disturbances in general, we should as soon as practicable unload the gastro-intestinal tract, and then regulate the diet of the patient, so as to avoid the use of food that may decompose. Then we should also aim, if possible, to flood this same gastro-intestinal tract, so as to cleanse it frequently, thus reducing to a minimum the chance of endogenetic infection, using when available mild antiseptic solutions. Finally, we should select by preference those drugs which act as gastro-intestinal antiseptics, such, for example, as calomel and other salts of mercury. We know that they act favorably in kidney affections. His personal experience in the irrigation of the bowel in infantile enteritis with antiseptic solutions, had aided him in coming to these conclusions.

SOME HINTS AS TO THE TREATMENT OF "COLDS."

BY HERBERT B. WHITNEY, M.D.,
OF DENVER, COL.;
PROFESSOR OF CHILDREN'S DISEASES AND OF PHYSICAL DIAGNOSIS IN THE STATE UNIVERSITY OF COLORADO.

ACUTE coryza is not only a universal malady, of which everyone has had some personal experience, but it is also a frequent object of medical advice. One is often consulted as to the best means of aborting this affection, as well as for methods of relieving the distressing symptoms which attend its course. Usually insignificant and temporary, acute coryza is not infrequently the first stage of a descending catarrh that ends in a long-continued and sometimes even dangerous bronchitis. In certain individuals—among whom the writer is so unfortunate as to be numbered—this tendency to invade the bronchial tubes is painfully constant and invariable. For these reasons, "a cold in the head" is not unworthy of careful attention on the part of the family physician; and a few therapeutic suggestions, gathered from various sources in the course of several years, may not prove unwelcome.

As regards prophylaxis, each individual is a law unto himself; he knows from personal experience his vulnerable point. With one it is the feet, with another the chest, sometimes the back of the neck, and again the scalp; many women are always liable to cold whenever they wash the hair. It is hardly necessary, therefore, to tell the individual what he must avoid; he knows.

There are, however, certain facts of common observation which may here be emphasized. In the first place, the general hardening process of the skin, so much practised by the European peoples, is unquestionably a prophylactic factor of the greatest utility. Exception being made of individuals of naturally weak constitution, the habit can hardly be too early acquired of a systematic gymnastic exercise of the superficial capillaries. In early childhood this may be begun by following the daily bath with a cold sponge effusion. Later, the whole bath may be cooler, and after the age of puberty, there is nothing better than the cold plunge or shower-bath of perhaps thirty to sixty seconds' duration. Of course, much depends on the surroundings and the exercise of common sense: the bathroom should neither be icy-cold nor so hot that the rubbing-off ends in an exhausting perspiration. My own plan is as follows: The room being at a temperature of about 60° or 65° F., two or three minutes are spent at the bowl in the toilet of the hands and face. During this time the naked body is exposed—beneficially, I think—to the slightly chilling atmosphere of the room. This is followed by a quick shower-bath of practically the temperature at which the water comes from the hydrant. A rather vigorous rub, continued only until the skin is dry, leaves the body warm and glowing. It is to this daily exposure that I attribute my comparative freedom from colds of late years.

Another fact of prophylactic interest is generally recognized: colds rarely follow exposure during exercise, or immediately after it. It is only after a certain degree of cooling has taken place that the danger begins. A cold plunge into the river immediately after a hard pull is the routine practice of our college crews, even late in the autumn months. In climbing the Kœnig's pass in the Tyrolese Alps, I have, with perfect impunity, made a complete change of underwear in the midst of a driving snowstorm; being overheated from exercise, I knew that a *brief* exposure would have no effect upon the superficial circulation. It is only after a certain time has elapsed (as indicated by the sensation of cooling off) that the possibility of taking cold begins. If exercise is resumed before there is any sensation of chilliness or drying, a cold will almost invariably be avoided.

When a coryza is threatened, or even already established, it may, if taken early, frequently be aborted. Measures to this end may be both general and local.

General Treatment.—The efficacy of quinin in certain cases can scarcely be doubted. As a rule, it must be taken within the first twelve hours, and to the quantity of at least 10 grains, in a single or divided doses. Unfortunately, the physiological effect of the drug is often hardly less disagreeable than the disease itself, and, moreover, its curative action is very uncertain. Personally, I rarely advise it. Other cases are favorably influenced by diaphoresis. Under favorable circumstances, as, for example, where the patient can remain on the following day at home, and especially where, in addition to the catarrhal symptoms, there is some little febrile movement and myalgia, the following common procedure may be advised: Ten grains each of Dover's powder and phenacetin are put into four capsules; two of these are given at once, and the patient remains for about ten minutes in a hot bath. He then takes a hot lemonade or rum punch and gets between several thicknesses of heated blankets. In half an hour the second two capsules are given, unless perspiration is already abundant. Such perspiration should continue for an hour, after which the skin is slowly dried, and the patient retires for the night to a comfortable bed.

But it is not often that such circumstantial treatment of a simple coryza is necessary, or even desirable. For people who are compelled to be up and about, or who, perhaps, have some urgent engagement for the evening, there are two remedies, either of which offers a very considerable prospect of quick relief. The first is the tincture of euphrasia officinalis; ten drops of this every ten or fifteen minutes for two or three hours will sometimes almost completely dissipate the headache and the uncomfortable sensation of stuffiness and frontal pressure so characteristic of acute nasal catarrh. A second, and perhaps more valuable—certainly more tested—remedy is gelsemium sempervirens. The action of this drug upon the first and second branches of the trigeminus is well known; and it is probably through its effect upon the nasal branches of the ophthalmic nerve and of the ganglion of Meckel that it exercises an abortive influence in this affect on. It may be given at the outset as a single dose of 20 drops of the tincture, or the same quantity may be added to half a tumbler of water, and of this a teaspoonful be taken every ten minutes for two or three hours, or until diaphoresis results.

Later, when the coryza has progressed to the stage of abundant discharge, the only internal remedy that I have found of any service is atropin, in doses of $\frac{1}{16}$ of a grain, once or twice daily. In some people, this produces so much dryness of the throat, or mydriasis, that it has to be discontinued; in others, however, it causes an agreeable diminution in the quantity of the discharge.

Local applications, chiefly in the form of inhalations, are more popular, more convenient, and, perhaps, on the whole, more useful than any of the remedies hitherto mentioned. An old and familiar combination is the following:

℞	Acidi carbolici, ...	ʒ i
	Spts. vini. rect., ...	ʒ iii
	Liq. ammon. caust., ...	ʒ i
	Aq. dist., ...	ʒ ii

M. Sig. For frequent inhalation.

This mixture will undoubtedly afford considerable relief, but it is hardly to be compared in general efficiency with others given below.

During the first two or three days of a coryza the most useful of all the preparations I have employed is a snuff, the principal ingredients of which are cocain and menthol:

℞	Cocain hydrochlor., ...	gr. iiss
	Menthol, ...	gr. iv
	Acidi borici, ...	ʒ ss
	Pulv. coffeæ, ...	gr. viii

M. Sig. Snuff (Coupard).

Of this, a small pinch is directed to be taken in each nostril every two or three hours. It gives great temporary relief, and I am frequently asked to have the prescription repeated. This snuff may also be used with benefit after there is an abundant catarrhal secretion. It may, with advantage, be combined with the internal use of gelsemium, or, later, with atropin.

Another good method for the local use of menthol has recently been strongly urged by R. Wünsche (*Ther. Monatsehfte*, 1895, No. 9). He prescribes the following:

℞	Menthol, ...	ʒ ss
	Chloroformi, ...	ʒ v

M. Sig. Inhalation.

At the first indication of coryza—such as sneezing and frontal discomfort—4 or 5 drops of the above mixture are quickly rubbed over the palms of the hands, the latter held like a cone over the nose and mouth, and a few deep inhalations are taken. It is claimed that all tendency to sneeze at once ceases, and the coryza is almost invariably aborted. For additional surety, it is recommended that the inhalation be repeated two or three times in the course of the following day. Wünsche has also found that these inhalations are a good prophylacticum against influenza, and calls attention to the experiments of Rönicke, which seemed to demonstrate the marked germicidal action of menthol fumes. The great benefit to be derived from menthol in various affections of the upper air passages, as appears from the many recommendations which have come from different sources, certainly warrants an extended trial of this remedy in acute coryza.

Camphor is another drug that has for a long time borne the well-deserved reputation of being serviceable in this disease. At Bamberger's clinic, in Vienna, the routine treatment of the first stage of coryza is this snuff:

℞	Camphor trit., Sacch. alb.,	aa . . . . ʒ ii

M. Sig. A small pinch in each nostril every two hours.

I have also used the following method with advantage, although, on the whole, the snuff is to be preferred: The patient is directed to put an ounce of powdered camphor in a shaving-mug and to fill with boiling water; a cone of stiff paper is then arranged so as to fit over the mug and to cover the face, and the fumes are thus inhaled for twenty minutes every two or three hours. Here, again, the fault of the method lies in the fact that it is too troublesome; for a simple "cold" people demand a simple remedy, and anything else is regarded with disfavor from the start.

During the stage of exudation, it is my personal belief that local treatment is of little benefit. If a remedy is desired, I know of nothing better, and at the same time simpler, than a snuff of alum, 1 part to 10 of powdered sugar or boric acid.

In closing this brief *résumé*, I wish to disclaim any originality whatever in the suggestions offered. My object has been simply to state a few useful empiricisms which, in the course of years, have been blown in upon me by the four winds.

BOVINE TUBERCULOSIS AS A FACTOR IN THE PRODUCTION OF HUMAN TUBERCULOSIS, THROUGH THE USE OF MEAT AND MILK.[1]

By D. H. BERGEY, M.D.,
OF PHILADELPHIA;
FIRST ASSISTANT IN THE LABORATORY OF HYGIENE, UNIVERSITY OF PENNSYLVANIA.

TUBERCULOSIS causes about fourteen per cent. of all deaths—or more than smallpox, diphtheria, scarlatina, typhoid fever, typhus fever, yellow fever, cerebro-spinal fever, Asiatic cholera, relapsing fever, leprosy, measles, and whooping cough, combined. The extremely high death-rate from tuberculosis should call forth all our dormant energies to prevent its spread, and to arrest its further progress as far as possible. Preventive measures are of especial importance because of the insidious onset of the disease, and its relatively slow progress when once established; because it causes such prolonged suffering, entails such great expense to those afflicted with it, and is so readily transmitted from the sick to the well.

The bacillus tuberculosis is now considered by all the best authorities to be the real and active cause of the disease, yet they all agree that the environment and the vital resistance of the body are important factors in facilitating or retarding its propagation. There can be no doubt that the nature of the soil and the condition of the biologic functions of our bodies will influence the results when the germs of tuberculosis succeed in gaining an entrance. On the other hand, there can also be no doubt that it is impossible to produce the disease in human or animal bodies without sowing its specific germ in such bodies, regardless of what the nature of the environment may be, or of the extent to which the vital resistance of the body has been reduced.

There is no longer any dispute as to the identity of the disease as it occurs in man and the domestic animals—only excluding fowls. We have abundant experimental evidence that the disease is readily communicated from man to the lower animals, and that the lesions produced are identical with those observed in man. There is a difference of opinion as to the extent to which tuberculosis prevails among the domestic animals. It has been estimated that from five to fifteen per cent. of milch cows are tuberculous. The prevalence of the disease among cattle varies greatly in different sections, being more common in those sections in which the cattle are confined in close stables during the greater portion of the year.

The possibility of the transmission of tuberculosis from the lower animals to man has long been recognized. The danger of contracting the disease through the consumption of the milk and meat of tuberculous cattle has been known to the scientific world for more than a hundred years. The extent of the danger is to-day the principal controversial point. It is frequently contended by those who pretend to assume a conservative position that we lack sufficient positive data, experimental and physiological, to warrant us in formulating definite conclusions on the subject. Happily, however, recent literature on the subject abounds in data accumulated by a host of scientific observers, whose competency is unquestioned, that shows the danger of infection through tuberculous meat and milk is very great.

As the result of clinical observation, a number of observers report instances of infection through the alimentary tract in animals by mixing tuberculous sputum with the food. Reissmann[1] quotes Jacobs, Devillers, Lengler, Durieux, Demme, Bollinger, Lamallerée, Nocard, Johne, Peters, Morro, Zschokke, and Eberlein, who report instances of infection in this manner in heifers, cats, dogs, hens and parrots, as the result of taking human tuberculous sputum with the food. He also quotes Klebs, Goring, Zippelius, Lehuert, Kloss, Böttcher, Woodhead, Utz, Demme, Uffelman, Felizel, Martin, Ebstein, Hergard, Johne, Prümers, Gosse, Sonntag, McFadyean and Woodhead, Bang, and Lucas, who report instances of infection in heifers, calves and pigs, from milk, and also of swine feeding on the meat of highly tuberculous heifers. Kolb also reports cases of three pigs fed on raw tuberculous meat, which showed tubercular infection of the alimentary tract. Schmidt observed a number of cases of infection in chickens, especially of the liver, that had been fed on raw meat from a highly tuberculous ox.

---

[1] Read before the Montgomery County Medical Society, Norristown, Pa., December 16, 1896.

[1] Reissmann, *Hygienische Rundschau*. Berlin, 1896, No. 18, 19, 20 and 21.

Reissmann states that the presence of tubercle bacilli in the walls of the blood-vessels, in the lumen of the vessels, and in thrombi, as well as in the vicinity of the vessels, has been demonstrated in a number of cases of advanced tuberculosis in cattle by Fütterer, and that Rütimeyer found bacilli in the blood of a case of acute general tuberculosis, and in another case in the spleen. Sticker, in two cases, and Ulacocis, in one case, of generalized human tuberculosis, found bacilli in the blood taken from the tip of the finger. Meisels, and Lustig, also found bacilli in the blood, and Heller reports a similar instance. Weigert, Nasse, Herxheimer and Bergkammer found bacilli in the blood and lymph of cases of generalized and miliary tuberculosis. Confirmatory reports have also been made by Hanan, Hagemann, Bang, Sticker, Sacerdoti, Cantoni, Ehrlich, Guttmann and others, indicating that there is danger of infection from meat of tuberculous cattle even in the absence of lesions in those parts.

The report of the Royal Commission on Tuberculosis[1] is the most important communication on this subject of recent date. This report is based on—(1) the experiments of Dr. Sidney Martin, who fed pigs, guinea-pigs and rabbits on meat and milk derived from tuberculous animals, though all tubercular lesions had been first removed. Of the animals thus fed, 36 per cent. (5 out of 14) of the pigs became tuberculous; of the guinea-pigs, 16 per cent. (24 out of 145), and of the rabbits, 15 per cent. (2 out of 13). He also fed one pig, 8 guinea-pigs and 10 calves with material containing tubercular matter, each animal receiving only a single dose. Of these animals, the pig, 6 guinea-pigs and 8 calves became tuberculous. (2) The experiments of Dr. Sims Woodhead, who fed 7 pigs, 5 cats and 76 guinea-pigs on tuberculous matter, and all the pigs and cats and 50 of the guinea-pigs became tuberculous. Both of these investigators found that the milk of tuberculous cows contained bacilli only when the udder was also diseased, and was only then capable of conveying the disease to the animals fed upon the milk, or inoculated with it. When the udder was diseased the milk possessed a most extraordinary virulence. They report that the udder may be affected in the early stage of the disease, and when diseased the process spreads with great rapidity. At times the udder may also be diseased without presenting any definite signs in the earlier stages, thus making it very dangerous to use the milk. Both Dr. Martin and Dr. Woodhead insist that no tuberculous animal of any kind should be allowed to remain in a dairy.

Dr. Woodhead experimented in roasting and boiling meat smeared with tuberculous matter. He found that rolls of such meat of over three or four pounds in weight, were not sterilized by the ordinary methods of cooking. He also experimented with tuberculous milk heated to 80° C. (176° F.) for ten minutes, and found that guinea-pigs fed on such milk become tuberculous.

As the result of his experiments, Dr. Martin was especially impressed with the danger of infecting the entire carcass of an animal in removing the diseased organs from it. Manifestly this danger is least in those cases in which the disease is distinctly localized in a single organ, but the danger is greatly increased when the disease is more generalized. He says that "one is driven to the conclusion that when meat is infective it commonly acquires its properties by being accidentally contaminated with tuberculous material during its removal from the carcass. This conclusion, it is evident, is one of great practical importance, bearing directly on the question of the condemnation of the meat of tuberculous cattle for human consumption. And it is evident, also, that the infective properties of meat might vary with different series of experiments; . . . the result depends on the care taken in guarding against contamination more than on anything else."

Dr. E. C. Schroeder[1] reports several series of experiments with milk for the detection of tuberculosis. In the first series the abdominal cavity of guinea-pigs was injected with nineteen samples of milk from different dealers or dairies, only one of the samples proving to be tuberculous. In the second series of experiments the abdominal cavity of guinea-pigs was injected with twelve samples of milk taken from cows that were known to be tuberculous, only one of the animals succumbing to the disease.

Dr. E. O. Shakspeare,[2] in speaking of tuberculosis in relation to infectious milk, says that "since tuberculosis of the human race has become better known, it has been found that in infants and young children, in some large cities, the mortality from some form of tuberculosis is far greater than has been generally believed, amounting, in some localities, to one-fifth of the deaths of the young. A significant fact in this connection is that it is most frequently some part of the digestive passages that becomes first affected in children."

[2] Shakspeare, Public Health Circulars issued by the Philadelphia, Pa., Board of Health, No. 11. Philadelphia, Pa., 1893.

Dr. Irving A. Watson[1] cites the following observers on the question of transmission of tuberculosis through the milk of tuberculous cows: "Leonhardt reports the case of a healthy infant, of healthy parents, which was weaned and put on cow's milk. The child soon died of tuberculosis of the meninges, intestines, and mesenteric glands. The cow which gave the milk was found to be tuberculous. Another child fed on the milk of the same cow died, at about the same time, from tubercular meningitis. Sonntag reports the case of a six-months' infant, of healthy parents, which at autopsy showed miliary tuberculosis of the meninges. It was fed with milk from a tuberculous cow. Hermsdorf gives three cases in which there was extensive intestinal tuberculosis, besides less general affection of other organs. One had taken uncooked milk from a tuberculous cow. Demme reports the case of a four-months' infant, which at autopsy showed tuberculosis of the mesenteric glands. There was no tuberculosis in the family for two generations on either side. The milk came from a cow with general tuberculosis. Bollinger cites Stangs' case of a boy of five years who sickened with ascites and enlarged glands in the abdomen. At autopsy the chief lesion was tuberculosis of the abdominal lymphatics, but there was also tuberculosis of the serous membranes and of the lungs. There was no tuberculosis in the family for two generations. The child had for years been in the habit of drinking milk warm from a cow, which, growing thin before the boy died, was killed, and found to be tuberculous."

Dr. L. Emmett Holt[2] reports on 1045 consecutive autopsies from the records of the N. Y. Infant Asylum and the Babies' Hospital—ten per cent. of which were found to be tuberculous. In the latter, which receives only sick children, the percentage was the higher. Of 143 children, fifty-seven were less than one year, thirty-nine, between one and two years, thirty-two, between two and five years, and only fifteen over five years of age.

It is unnecessary to further multiply the citations of the results from the experimental investigation of the question under discussion, or the results of clinical and pathological observations as to the direct transmission of the disease through the use of tuberculous meat and milk. It should be evident to every one open to conviction that there is positive danger in the use of such products.

The phase of the subject which gives rise to differences of opinion to-day, among medical men as well as the laity, is not whether the meat and milk of tuberculous cows are dangerous, but at what stage of the disease do they become dangerous. It is evident, from the results of experiments upon animals, that in the earlier stages, while the disease process is still localized in a single organ, that the meat of such animals is not very dangerous; it is claimed by some to be innocuous. It is also evident, that as long as the udder of a cow is not involved, the large majority of cows do not yield tuberculous milk. The varied opinions demonstrate, to a great extent at least, the differences in the laws and customs, in different countries, with regard to the use of the meat and milk of animals suffering from localized tuberculosis. This difference is only in part explainable on these grounds. A further cause of the differences in these laws is also due to the fact that in some of these countries the laws have not been brought up to the level of our present-day knowledge of the subject.

In the several German States the laws vary to a considerable extent. As a rule, the meat is condemned when there is fever, when the animal is emaciated, when the disease has become generalized, and when there are nodules present. In France, Italy, Belgium and Denmark the same general law also applies, and when the disease is localized, and the diseased portion is easily removable, the meat may be used. In Saxony and Mecklenburg the diseased meat must be divided into small pieces and sterilized at 100° C. for half an hour before it is sold as food. In Saxony, Bavaria, and Italy such meat can only be exposed for sale when distinctly marked with a declaration that it came from a tuberculous animal, while in Denmark it is sold as second-class meat.

In searching the literature of the subject for expression of opinions by eminent scientists on the question of the use of the meat and milk of tuberculous cows, I find that Drs. Martin and Woodhead, already quoted, are of the opinion that all diseased animals should be killed and the meat condemned. Dr. Deshayes[1] says that "all animals infected with tuberculosis, even localized, should be unalterably rejected for human consumption."

Dr. Theobald Smith[2] coincides with Nocard, whom he quotes, in saying that all highly tuberculous animals should be condemned. Those having the disease in its incipient stage should be quarantined, fattened, and then sold only to the butcher. If they are found to be but slightly diseased, the meat may be exposed for sale after removal of the diseased portions.

Frequent visits to the abattoir of Philadelphia convince me that the meat of cows with localized tuberculosis is allowed to be sold. When the disease is somewhat generalized, I am informed, the inspectors condemn the carcass, and it is converted into fertilizer. Many writers claim that it is merely a matter of sentiment whether we condemn the meat of animals in which the disease is localized. To me it is a matter of the greatest vital importance. When we consider the markedly lower mortality from tuberculosis among the Jews, it is evident that their greater immunity from tuberculosis must be traceable to their well-known rigid meat inspection alone, because, as a rule, they do not live under the most favorable hygienic conditions. They discard the entire carcass of every animal that shows signs of disease of the organs of the great body cavities. Such meat is then sold to ordinary consumers.

[2] Smith, Bureau of Animal Industry, Bulletin No. 7. Washington, D. C., 1894.

To guard against the dangers of infection through the use of tuberculous meat and milk, we should urge the necessity of the thorough inspection of all cows kept for breeding purposes, or whose milk is offered for general consumption. All animals intended for use as meat should also be inspected, and those showing a trace of the disease should be condemned as unfit for consumption. The most reliable and ready method known to us to-day, by means of which we can detect the disease even in the incipient stage, is the tuberculin test. This test is now employed in many States and in many of the foreign countries, and, if the tuberculin has been prepared by competent bacteriologists, it is without detrimental effects on healthy animals.

In the absence of positive knowledge as to the healthfulness of cattle whose meat and milk is intended for human food, it is of the utmost importance that all milk be heated to 180° F. for five minutes before it is used, and that our meat be thoroughly cooked in order to avoid the danger of infection through its use.

AN ADDRESS.

THE COUNTRY DOCTOR.[1]

BY FREDERICK HOLME WIGGIN, M.D.,
OF NEW YORK;
VISITING GYNECOLOGIST TO THE NEW YORK CITY HOSPITAL, BLACKWELL'S ISLAND.

AS occasional introspection into individual life has an acknowleged value, it may be of practical benefit to turn our attention for a time to the consideration of a few points in the daily life of the learned profession to which we have the honor to belong. Therefore, I propose briefly to touch on some points of country medical life, and later to call attention to what I believe to be the needs of this Association to further its development and to bring it to the highest state of efficiency of which it is capable.

It is frequently thought by the country physician that all the professional advantage lies with his city brother; that he alone has opportunities for gaining a fair support from his professional labors, of increasing his store of knowledge, and of adding to the general professional welfare. To one acquainted with the environment of the city physician, and the many difficulties which beset him, which can be overcome in most instances only by years of arduous work before even his living is assured, this feeling is hard to understand, and to such an observer a prosperous village or small town seems a more attractive place in which to pursue the practical work of the physician; for, here are no dispensaries or hospitals casting, when abused, their baleful influence over the community and the profession under the guise of charity; here the public is more or less willing to share the burden of caring for the destitute with the physician; here he is able to support himself from the beginning of his professional career, can acquire a pleasant home early in life, and can bring up his family in the country, whence, as President Eliot, of Harvard College, has pointed out, the best students come.

With the large and varied experience which most country physicians have, opportunities for making reputation occur earlier and more frequently out of the city than in it. In the country fees are more certain to be collected, and the country physician's relations to his patients and the community are pleasanter, closer, and more important than they are in a large city. If, on the other hand, country practice involves greater physical exposure and fatigue, the practitioner is spared much of the mental anxiety and financial care of his city brother; and finally, if it is objected that the fees which dwellers in rural districts are able to pay are much smaller than those obtained by city physicians, it may be answered that the personal needs and the general expense of living are less in the country than in the city, while it is a fact that the income of the average city physician is not relatively, or actually, greater than is that received by the average country physician.

As a more intimate acquaintance with country medical life is obtained, one finds less difficulty in understanding why, in the midst of so much that is desirable, the mind of the average country physician is despondent. It is found that here, as elsewhere, the profession has been engaged for many years in educating the public and themselves to believe that medical professional services have little or no pecuniary worth. If the fee table of the local medical society is consulted, the maximum rate of fees seems satisfactory and capable of returning a good income to an industrious physician, and the fees also seem well within the means of the more prosperous members of the community; but a question elicits the answer that charges are based not upon this scale, but upon the minimum rate, which therefore becomes the standard, and which is often shaded, even for the well-to-do. Consequently services and experience are sold for and believed to be worth only a fraction of their value, and frequently for less than a livery-stable keeper would value the services of a horse for the same time and distance. As a result of this supposed necessity of either meeting competition or retaining personal popularity, the financial results are out of proportion to the efforts expended, and are inadequate. So the physician frequently adds commercial ventures to his professional duties, which, proving lucrative, soon become the vocation, and medicine the avocation. Losses incurred in performing professional duties at ruinous prices are made up on sales of drugs, general merchandise, or farm products. Time which ought to be given up to self-improvement or in resting body and mind is taken up with these outside pursuits, vacations are seldom indulged in, meetings of medical men are gradually neglected, and less and less thought or care is given to the general professional welfare, causing possibly a still further reduction in the fees demanded. Again, accounts are carelessly kept, bills are rendered only at long intervals, and the patient, taking this as an evidence of the physician's prosperity, procrastinates about settling his account. But the worst result of this system of small fees is the gradual deterioration in the quality of the physician's services, who, instead of doing the best work of which he is capable, becomes satisfied to render the poorest, as being all that the patient has paid for. The patient is frequently allowed to make the diagnosis, and under this method the writer has known good men to be credited with serious errors of diagnosis. He has known a case of imperforate hymen, with enlarged uterus and a projecting vaginal tumor, caused by retained menstrual fluid, diagnosticated as a case of amenorrhea, and the patient advised that Nature must take its course, which advice was certainly not worth the 50-cent fee paid for it; of a patient with a large carcinomatous testicle, which weighed over two pounds after its removal, having been told that he was demented when he stated his case. No examination was made, and the patient was dismissed after paying his fee, with the admonition that "some people are always imagining that they have trouble with their privates." The patient then called on the writer, who, after a careful examination, diagnosticated the case and advised operation, which was consented to, and a larger fee demanded, which was cheerfully paid. The writer has known of a case of empyema, occurring in a child of four years, considered and treated as one of worms, because the child stated that his pain was in the region of his navel; and as the 50-cent fee was not supposed to include a physical examination, none was made. He has also known of pleurisy with effusion diagnosticated and treated as influenza because the patient suggested this diagnosis.

---

[1] President's address delivered before the Litchfield County, Conn., Medical Association at the annual meeting held at Litchfield, October 8, 1895; also read by request at the meeting of the Conn. Medical Society at New Haven, May 28, 1896.

Aseptic surgical technic is often made light of as being too expensive for country work. One extreme case treated on these lines, which came under the writer's notice, was that of a patient who had received an injury which crushed one of his fingers. This was amputated with an ordinary pocket-knife, the operation being naturally followed by septic infection, and this, in turn, by amputation of the patient's arm. The final outcome was the death of both the patient and the physician, who had inoculated himself in the careless handling of the wound.

Such experiences, which were common when the writer began his professional career in this locality, some years since, have happily ceased. The ordinary result of working under such a system as has been alluded to, is that after some years of active work and physical hardship, a complete breakdown occurs of mind, body, and, unless wealth has been acquired by some other means, of estate as well. On the other hand, it was found by the writer that an attempt to render a more careful, and therefore better professional service, was promptly met by willingness on the part of the community to pay more liberally, when the reason for the increased charge was explained. The result of this was that after a few years the income derived from professional work alone was nearly double that received by the writer's predecessor in the same field after twenty-five years of toil. The benefit was certainly not wholly confined to the writer, but extended to all who practised in the neighborhood, and to those who succeeded to the work. If it were possible, without being ungenerous or oppressive, to educate the public to a willingness to pay for a service what it was fairly worth in one locality, it can be done elsewhere.

People are beginning to realize that the country doctor must be a better physician than the city doctor. In the course of a recent editorial in one of the medical journals it was stated that, "Country practice, strange as it may appear, demands a higher grade of professional attainments at the start than those by which a young man makes an ordinary success in the city. The country physician is a marked man from the beginning, is generally known by every one in his town, and must necessarily, at the very outset of his career, set the pace for the remainder of his life."

Be practitioners of medicine only. Bend all your energies to the care of your patients and to self-improvement. Make your patients realize that you are abreast of the times and doing only the best professional work of which you are capable. Attend and take part in the meetings of medical societies. Go from time to time to the city, and see what others are doing, and get out, as Dr. W. H. Thomson aptly puts it, "a new edition of yourself." Take a yearly vacation for bodily and mental recreation, and you will find that your patients will not object to paying a higher fee for your services when you demand it. Give more thought to the general professional welfare, bearing in mind that if one would elevate himself he must elevate the profession to which he belongs.

There are, of course, various ways in which this may be accomplished, but the most practicable for most of us is by having personal pride in the reputation of the local medical association, and by taking an active part in its work. A serious effort should be made to attend all the meetings. Records of cases should be kept, so that written histories of those of interest can be presented at the meetings for consideration and discussion. It is a common experience for a presiding officer, after asking members if they have not cases of interest to report, and meeting with a negative reply, to hear the same members, after the close of the meeting, recount various experiences of general interest. Each member should be required in turn to write and read a short paper, the chief points of which should be furnished to some of the other members prior to the meeting, so that they can prepare themselves for its discussion.

When a member is honored by an election as a delegate to a local, state, or national association, he should consider it his duty to attend the meeting. Owing largely to the failure of members appointed fellows of the State Society to attend the meetings, this Society has lost much of its prestige, and has of late years exerted little influence on the general professional welfare. Official position should be considered one of honor and trust, and every effort should be made to perform the various prescribed duties by those chosen to fill them. Quarterly meetings should be held regularly in different towns of the county, so that all members may each year have an opportunity of attending a meeting of the Association convenient to their own homes. If the best work of which this Society is capable is to be obtained the annual dues should be increased sufficiently to permit of the employment of a stenographer, to attend the meetings and report the proceedings. Arrangements could then be made with a medical journal to publish them. It is hard to get men to do their best literary work unless opportunity is afforded to record it. I believe that more effort should be made to develop the social side of these meetings, and the annual dues should admit of the general entertainment being paid for out of the Society's treasury. Were these suggestions carried out there would be little difficulty in maintaining full attendance at the meetings. These days would come to be looked upon as pleasant and profitable; days for consultation, self-improvement, and social enjoyment; and, in time, the Society would become a model for others to follow, whether of city or state.

A society is what its members and officers make it, and nothing more; and to make it prosperous and influential all must join hands, each doing his duty. Individually, you would soon realize the benefit. You would find your interest constantly growing in scientific medicine as you studied systematically in the preparation for the writing of papers or for the purpose of taking part in their discussion, and this would be followed, as the members of the community realized that their doctor was up-to-date, by their increased respect and a willingness to pay more generously for his services. People take us largely at our own valuation. Remember that much original work has been done by country physicians, and that by reason of such efforts great advance has been made all along the line of medical work. Jenner, the discoverer of the protective influence of vaccination; Ephraim McDowell, who in 1809 performed the first successful ovariotomy of which we have record; Joseph Glover, of South Carolina, who in 1813 first successfully performed the operation of hysterectomy; Marion Sims, the father of gynecology, who perfected the technic of his operation for the closure of vesicovaginal fistula in the negro cabins of the South; Nathan Smith, of New Haven, who was the first to successfully perform an amputation through the knee-joint, and who, without knowing of McDowell's work, successfully performed an ovariotomy in 1821, advancing the technic of the operation by returning the stump into the peritoneal cavity; and Cogswell, of Hartford, who first succeeded in ligating the common carotid artery, were provincial physicians who became world-renowned.

Of McDowell's work, Dr. Dennis has said, in his essay on "The Achievements of American Surgery": "Few men can realize the influence of McDowell's first ovariotomy upon the whole field of abdominal surgery. It is indeed a sublime thought to consider that a man was found with the courage of his convictions to do what no man had ever done, and to operate within the noise of an infuriated mob beneath his windows. This mob would have lynched him if Mrs. Crawford had died. Having escaped the angry mob, he was pointed out as a murderer by his colleagues, and was also condemned by the highest scientific authorities in Europe. In America, therefore, under such circumstances, and under such conditions, the birth of the greatest operation in surgery occurred, an operation destined to save in the future millions of human lives." The *Medico-Chirurgical Review*, speaking of McDowell's achievement, said: "A back settlement of America, Kentucky, has beaten the mother-country, nay, Europe itself, with all the boasted surgeons thereof, in the fearful and formidable operation of gastrotomy with extraction of diseased ovaries."

Finally, Dr. Joseph Eastman of Indianapolis, in responding recently to the toast, "Ephraim McDowell," said: "Kentucky is justly proud of her statesmen, of her orators, and her soldiers, but shall not the achievements of her statesmen succumb at last to the pitiless logic of events? Shall not the voice of her orators grow fainter with coming ages? Shall not the victories of her soldiers be found at last only in the libraries of students of military campaigns, while the fame of this village surgeon, like the ever-widening waves of the inviolate sea, shall be wafted to the utmost shores of time, hailed alike by all nations, in all ages, for having lessened the burden and prolonged the span of human life?"

CLINICAL MEMORANDUM.

CATARACT EXTRACTION FOLLOWED BY COMPLETE ATROPHY OF THE IRIS; PRIMARY SARCOMA OF THE IRIS.[1]

By FRANK H. EDSALL, M.D.,
OF PITTSBURG, PA.;
OPHTHALMOLOGIST TO ST. FRANCIS HOSPITAL, AND TO THE PITTSBURG HOSPITAL FOR CHILDREN.

THE two cases, reports of which follow, are, I think, sufficiently unusual to make them of interest as curiosities.

CASE I.—Mr. H., a glass-worker in one of the neighboring towns, came under my charge in June, 1895. He was at that time about twenty-four years of age, in vigorous health, and with no personal or family history which would in any way shed light upon the causation of the trouble for which he consulted me—complete opacity of the lens of the right eye. He had first noticed trouble with this eye some three or four months before I saw him, which trouble, then as now, had been limited to defect in the vision of the eye. It had progressed steadily up to the point which it had reached at the time he came under my charge. There was absolutely no history of injury, nor of inflammatory disease of the eye within the patient's memory, the only thing which had attracted his attention having been the increasing dimness of vision and the white spot in the pupillary space. He was annoyed by this disfigurement, and it was more for the purpose of being freed from it for cosmetic purposes than for possible improvement in vision that he consulted me with regard to its removal.

---

[1] Read before the Pittsburg Academy of Medicine.

The eye was carefully examined, but nothing beyond the complete white opacity of the lens could be determined. There was no inflammatory trouble, no defect in light projection, no increase in tension, no scars nor marks of any kind. The left eye was in every way normal beyond the presence of a moderate hypermetropia. After explaining to the patient the possibilities and limitations of results from operation, and being urged by him to operate for cosmetic purposes, I consented to do so. He was accordingly sent to St. Francis' Hospital, and a needle operation was undertaken. No symptoms of any moment were observed subsequent to the operation, and the patient was allowed to return home in a few days. At the end of about two months, absorption being incomplete, I repeated the needling, this time at my office. As before, there were no unfavorable symptoms following the operation, and further absorption took place as a result of this interference, but the process stopped short of entire disappearance of the cataract, and a third operation became necessary. This was undertaken about six weeks after the second, and, like it, was done in my office. No undue traction was made upon the zonula in either operation, and in the last, as in the others, no accident or complication occurred. For several days following, the case behaved very much as it did subsequent to the previous operations, except that there was some increase in the redness and injection of the ocular conjunctiva, which injection was rather more persistent than before. On the sixth day following the operation the patient complained of considerable pain in the eye. The eye was, at this time, noticeably though not violently injected; there had been some further absorption of the lens, and a few small flakes of lens-substance could be noticed in the anterior chamber. The aqueous humor was slightly turbid. The usual treatment for a mild iritis seemed all that was indicated in the case at this time, as the inflammatory symptoms were not violent and the eye was already under the influence of atropin. The pain lasted but a few days and the other symptoms of inflammation became gradually less marked, but did not wholly disappear for several months. In about two weeks from the date of this visit, the color of the unabsorbed lens-substance changed from clear white to a straw-yellow, and the iris had become infiltrated with a muddy-yellow lymph. From this time on there was a steady atrophic change in the iris. The exact date of the commencement of the absorption of the iris I am unable to state, as the patient about this time passed from my observation for some weeks. When I next saw him, however, absorption had occurred in a portion of the upper nasal quadrant of the iris. This atrophic portion steadily widened until in the course of some two months it had included the entire circumference of the structure excepting a small segment in the lower temporal quadrant. At this point a slight adhesion had formed between the pupillary border of the iris and the capsule of the lens, and here, whether in any way due to these adhesions or not I do not know, the iris has failed to atrophy, and is, to all appearances, still normal, while elsewhere it has completely disappeared. The vitreous chamber is at the present time filled with what appears to be a mass of organized lymph. No pus formed at any time in the course of the trouble, nor, as I have said, was there at any time any severe pain.

The retrograde process which occurred I believe to have been due to a cyclitis, though differing in many respects from a typical case of this affection. As to the cause of its onset I am in the dark. It may have been due to the fact that the necessary manipulation of the eye in operating had roused into activity a slumbering affection of the uveal tract. The occurrence of the cataract itself can be explained upon the supposition of the presence of a subacute inflammation in the uveal tract, and, except upon this hypothesis, I am at a loss to explain either the onset of the inflammation, which resulted in the atrophic process, or the causation of the cataract.

I cannot find mention in medical literature of any case that resembles this in its more important features, and am, therefore, forced to the conclusion that it is probably, in most respects, unique.

CASE II.—*Primary Sarcoma of the Iris.* I have unfortunately mislaid my notes of this case and the dates given are, in consequence, somewhat inexact but are approximately correct. The patient, Mrs. J. H., aged twenty-three, of Punxatawney, this State, was referred to me by my friend Dr. J. J. Green. Her story as given to me was as follows: Some two years before her visit she had noticed a small growth on the iris of the left eye near the temporal margin and about at the horizontal axis of the eye. This tumor continued to increase in size, and for several months there had been attacks of pain in the eye, increasing in severity and occurring at steadily lessening intervals, until, at the time she came under my charge, in the latter part of February, 1896, she was at no time entirely free from pain in the organ, and at times the suffering was exceedingly severe. Her general health was good, and family and personal history negative.

Inspection of the eye showed the presence of a tumor in the anterior chamber attached to the iris by a base about four millimeters in length, The tumor was about the size of a fair sized split-pea and completely covered the pupillary area. It was dark gray in color and was rather smooth in contour. It was attached about midway between the scleral and pupillary border of the iris on the temporal side. The husband of the patient stated that rather frequent hemorrhages occurred from the tumor into the anterior chamber, and at these times the pain was worse than at other times.

In endeavoring to gain some idea as to the rate at which the tumor was growing, I questioned the patient as to the length of time she had been blind in the eye, supposing that with the pupillary space covered by the growth, vision must of necessity be wanting. To my surprise, she replied, "I am not blind in the eye; I can see very well with it." Sceptical of this fact, I carefully occluded the sound eye and placed her in front of the test-card, and, to my further surprise, found that her vision was almost full $\frac{20}{30}$. It puzzled me for some time to determine the route by which this vision was obtained, but upon closer inspection I determined that it must be through a small opening in the tumor directly in front of the center of the pupil, which I had before thought was simply a point from which a hemorrhage had occurred. Examination of the eye subsequent to removal proved this supposition to have been correct. The tension of the eye was markedly increased.

I diagnosed the trouble as a probable sarcoma of the iris, mentioning, however, the possibility of its being a gumma, and suggested a short course of mercury and iodid of potassium, holding in reserve the enucleation of the eye if there were no effect from the medicinal treatment. Before arriving at any conclusion in regard to the course she would follow, the patient was, at her own request, referred to my friend Dr. Lippincott for further opinion regarding her case. His opinion was confirmatory of my diagnosis and of the treatment advised. The patient thereupon concluded to be guided by my advice, and I accordingly placed her upon specific treatment, which was continued for a brief time, but without results, except, indeed, that the tumor possibly increased somewhat in size. Satisfied that nothing was to be gained from following out this course further, enucleation was urged and consent for it obtained. The patient was sent to St. Francis' Hospital and the eye removed in April, 1896.

Recovery from the operation was uneventful, and at the end of the second or third week after the operation she returned home, having delayed her departure longer than was necessary in order that she might take home with her an artificial eye. Since her departure, I have heard nothing directly or indirectly from her, and I am therefore in ignorance of the subsequent history of the case. Section of the eye showed the attachment of the tumor to be as previously described. The central opening before mentioned was undoubtedly the pathway by which light entered the eye. The opening, on the corneal side, was exceedingly minute, but on the pupillary side of the tumor it was several times greater in diameter. The tumor was rather firm and pigmented. Hardening of the growth and subsequent microscopic examination at the hands of Dr. Matson showed it to be a small spindle-cell sarcoma.

Primary sarcoma of the iris is a rare affection. I have never before met with a case, the nearest approach to it having been in a man referred to me in 1893 by Dr. Scroggs of Beaver, Pa. In this case there was a tumor several millimeters in diameter lying partly on the cornea and partly on the sclera at the temporal side and in the horizontal plane of the eye. It had, at some time in the past, penetrated from the interior of the eye, as its pedicle was attached to the ciliary body and iris through an opening in the eye at the sclero-corneal limbus. Vision in the eye was almost normal, and in consequence of this fact, the patient refused to consent to removal of the eye, although my diagnosis of sarcoma was confirmed by Dr. Lippincott. At the patient's request, I removed as much of the tumor as it was possible to reach without invading the interior of the eye, after having made plain to him that the growth would almost certainly recur. Microscopic examination of the growth confirmed the diagnosis of sarcoma. Not many weeks elapsed before he was back again with a recurrence of the growth, and this time I positively refused to adopt any other course than that of removal of the eye, which was done at the hospital. Unfortunately, my resident failed to understand my directions for the preservation of the eye and, in consequence, no section of it was obtained.

All the text-books on ophthalmology make mention of primary sarcoma of the iris as an extremely rare occurrence. The Graefe-Saemisch "*Handbuch der Augenheilkunde*" speaks of it as a very unusual condition, of which a few cases have been reported, and Galezowsky of Paris states that he has seen one case in 50,000 cases of eye trouble. In the opinion of the writer, the treatment of sarcoma of the iris should be limited to nothing less than removal of the affected eye. The difficulty of determining whether the disease has affected the structures behind the iris renders any less radical measure a dangerous procedure, and would much increase the risk of recurrence in other organs.

SELECTION.

THE SPREAD OF THE BUBONIC PLAGUE.[1]

By JAMES CANTLIE, M.B., F.R.C.S.,
LECTURER ON APPLIED ANATOMY, CHARING CROSS HOSPITAL, LONDON; LATE OF HONG KONG, CHINA.

Without entering into the discussion as to whether or not all epidemics styled "plague" in biblical and medieval literature were of the nature of the bubonic plague of recent times, there can be no doubt that since 1850 the name "plague" has been applied to a definite train of symptoms which are considered to constitute a specific disease. As we proceed, it will be seen how during different outbreaks some one symptom attains a fatal preëminence, but not to the exclusion of others which might at any time assume the death lead, and serve to baptize the disease as "Bubonic," "Hemorrhagic," "Typhoidal," "Pneumonic," and so forth.

Name.—During the latter half of the century the names bestowed on plague have been as follows:

1. In 1856, in Tripoli, it was known as "typhus with glandular swelling." When the disease reached the island of Chios in the same year, it was called "petechial typhus analogous to that of Tripoli."

2. In Mesopotamia, where the disease was prevalent from 1856–85, and possibly up to the present day, the

---

[1] From the *Medical Press and Circular*, December 30, 1896, and January 6, 1897.

titles "adynamic typhoid fever," and "intermittent fever with glandular swellings," were usual.

3, In Persia, where plague seems to be endemic since 1863, the term "hemorrhagic fever" is used to designate a pestilence which differs from the diseases with which the Persians are familiar,

4. During the years 1877–79, the Russian province of Astrakhan was visited by a disease which was, and is, regarded as plague, but which was variously described as

(*a*) Intermittent fever with buboes.

(*b*) Croupous pneumonia with buboes.

(*c*) Typhus with glandular swellings proving fatal by pneumonia.

(*d*) A peculiar form of mumps.

That all the above-mentioned outbreaks were actually plague, a specific disease, caused by a specific bacillus, will never be known; but the presumptive and clinical evidence is decidedly in favor of their being one and the same disease.

The name "plague," however, is not one which helps us to place the complaint in its proper scientific niche in the category of disease. The word conveys the idea of an unusual disease attacking many persons and attended by a high mortality, but that gives it no scientific value any more than the "Wan-Yik" of the Chinese. Were I to attempt to classify plague, I would place it among the specific fevers, and particularize it under the name of "polyadenitis," and individualize it still further as "malignant polyadenitis."

The term "bubonic," so frequently applied to the disease, is not so appropriate as would at first sight appear. A bubo is essentially the swelling of a gland caused by the entrance of septic materials in the tract of lymphatics over which the gland presides. This cannot be said to obtain in plague, for the so-called buboes of plague can in no sense be regarded as a sympathetic swelling, but merely the outcome of a blood poison.

Definition.—Plague, or malignant polyadenitis, we may define as:—*An acute febrile disease of an intensely fatal nature, characterized by inflammation of the lymphatic glands, marked cerebral and vascular disturbances, and by the presence of a specific bacillus.* It is only since 1894 that we have been able to set forth a definition with precision; it is only since then that we have acquired the knowledge of a definite bacillus by which the disease can be recognized scientifically when ordinary symptoms are in abeyance. In this definition no mention is made of hemorrhage, pneumonia, petechiæ, or carbuncles.

Distribution.—At the present day, plague is confined to Asia; but since 1850 it has made its appearance in Europe, Asia and Africa.

The basin of the Mediterranean and the strip of country which runs parallel to that sea across the Asian continent, from Turkey to China, may be roughly taken as its present belt during the nineteenth century, but the Mediterranean part of the belt has disappeared almost wholly within the present generation. A map of the plague-stricken districts within the last fifty years shows plague astride the Himalayas, with a giant limb reaching on one side the Red Sea, and on the other the shores of the Pacific.

THE CONTINUITY OF PLAGUE OUTBREAKS.

It would appear that in the plague belt the disease is ever active, now in one place, now in another. At times we find it in Arabia, then in Persia, and the Himalayas, and the wave travels eastward over Yunnan and Southern China to the sea. The disease oscillates, now east, now west, but with a fatal precision, making the slow swing of the pendulum of plague within a fairly definite area.

Cause of Plague.—The cause of plague is the advent of a definite bacillus and it is the life-history of this bacillus which must in future occupy the attention of bacteriologists and clinical observers. The proximity of the bacillus is, at the present day, known only by its effect on human beings, and it may be, rats, as well. What fosters it appears to be bad sanitation; once established, time alone will stay its ravages so far as any given epidemic is concerned, but there seems every hope that improved sanitation will check its recurrences.

The *prodromata* of plague may be divided into the remote and the immediate; but I will consider them together. Time and again has it happened that before an outbreak of plague, during a period varying from a few months to several years, buboes with fever have been observed in a more or less epidemic form. In 1877 a variety of plague which infested Astrakhan previous to the outbreak that occurred in 1878, some 150 miles higher up the Volga, was classed as a *pestis minor.* No one died of the disease *per se*, and but few people were confined to bed. From Calcutta comes the news of the discovery of a bacillus allied in every respect to the Kitasato bacillus of true plague, and associated with the variety of plague known as *pestis minor*, which has convinced me that the two are identical. The bacillus is stated not to possess the toxic or virulent properties of the true plague bacillus, but to be similar in all other respects.

THE COMMUNICABILITY OF PLAGUE.

Infection and Contagion.—Direct contagion, that is, transference of the disease from the sick to the healthy by bodily contact, would appear at the first glance to be an element in the transmission of plague. How otherwise can we explain the circumstance that when a case of plague occurs in a house, those dwelling in the house and brought in contact with the sufferer are almost certain to be seized, and not only so, but few, if any, of the other inmates escape? The next in order to be seized by plague are the relatives of the sick and the visitors to the house, who, going to their own homes, set up a fresh focus of infection. Of the community, doctors, clergymen, and attendants who are brought in contact with the sufferers more readily acquire the disease than others who are alien to the family and house. These facts would appear to prove conclusively the contagious nature of plague.

But there is another side to the argument. As long ago as 1835, when plague was epidemic in Egypt, out of *ten French doctors* who attended the sick, only one contracted the disease. Further, we have the well-known case of Bulard during the same outbreak, who, anxious to prove his contention that the contagious nature of plague was much exaggerated, for two days wore the shirt of a patient who had died of plague, yet Bulard did not contract the disease.

More recently we have the evidence of the Hong Kong epidemic in 1894. None of the European doctors in attendance on the plague patients, in all some fifteen in number, were attacked by plague. Those men were freely exposed in the wards and at *post-mortem* examinations, yet none were infected. Further, none of the British and Italian-born nurses—these were the only two nationalities represented—were attacked by plague during 1894.

But a more interesting fact still, is that none of the Chinese students of the College of Medicine were attacked. For six weeks these men were on duty in turns night and day in the Plague Hospital. Eight of them acted as ward attendants and clerks throughout the period, and were consequently in constant contact with the sick. A racial immunity might be claimed for Europeans, but in face of this fact it cannot hold good. If there be any truth in the acquisition of disease during an epidemic by fear or nervousness, the case of these students refutes the aspersion. They saw that the Europeans escaped, and how terribly their countrymen suffered; they had to contend with the superstitious beliefs of their country, inherited and acquired ; they were breathing the same air, eating similar food, hearing daily, hourly even, of the deaths of their friends, relations, and acquaintances; yet none of them succumbed to plague. We have, therefore, two opposite conditions before us, namely, plague entering a house and seizing practically all the inmates; and, on the other hand, doctors, nurses, and native students acting as medical clerks and dressers, escaping completely. Where then lies the truth of the contagious nature of plague ?

As usual there is a channel of escape from either of these two extremes of argument. The immunity above related does not extend indefinitely. The Europeans attacked during the 1894 epidemic were chiefly soldiers of the Shropshire Regiment, then stationed in Hong Kong. When plague required sanitary interference beyond the power of the local board, these soldiers came forward and volunteered to help in the work of cleansing and purifying the city. The work assigned to them was of the most laborious order, and they were exposed to a concentration of the contagion, for the field of their duty lay among the dwellings of the poorest class of Chinese who were suffering from plague. Those houses were of the vilest kind of habitation mankind is acquainted with; small, windowless, low-ceilinged, reeking with filth and excretions, they presented infection in the most concentrated form. Further, the soldiers had to use spade and shovel to dig down into the accumulated layers of dirt on the floors of the houses and throw it into the street. It was this occupation, this raising of the dust, more than any other to which is attributed the infection of the soldiers.

The evidence of the subsequent outbreak in Hong Kong in 1896 goes to show that Europeans were much more frequently attacked than in 1894, and two of the nurses in attendance on the sick contracted plague. One of the nurses was a British-born nursing Sister at the Plague Hospital, where she had been for many months. She never was ill until the very end of the epidemic, when she got a sharp attack of the plague from which, however, she fortunately recovered. The Sister believes she was infected by a little child she nursed, and whom she frequently carried about in her arms. The other European nurse was an Italian-born nurse in the convent, who believed she was also infected by carrying about a child sick from plague. The Italian Sister died of the disease. It is interesting to note that the patient from whom the English Sister contracted the disease recovered, whereas the patient of the Italian Sister died. Another Sister in the convent died, presumably infected while nursing her companion. These three deaths seem to point to a contagion rather than infection as the means of spread, for although there were some 600 persons in the convent, none of the other inmates were afflicted.

Gathering this evidence together and trying to focus it we found that the soldiers, who were affected, were exposed, if there is any truth in intensity of contagion at all, to the most concentrated form of the poison. They worked, not in the streets in the open air, but in reeking hovels for several hours together. Intimate and prolonged contact with the contagion in an active condition seems to be the explanation of their *infection*.

The same is to be said of the two European nurses who were seized. Both attributed their ailment to intimate and prolonged *contact* with a generating source, *viz.*, a child carried in the arms, not for a few minutes, but for several hours daily, extending over several days.

That there are, however, degrees of power in the contagium even when emanating from the human body seems to be supported by the nurse and infecting child both recovering in the one instance, and the nurse and infecting child both dying in another. Bulard sleeping in the dead man's shirt proves nothing further than that the plague-infected garment did not *generate* poison of an intensity sufficient to infect. The poison grew every moment more dilute, but a nurse carrying a child throwing off contagium continuously is an exposure of a different stamp.

The immunity of the doctors and Chinese students does not annul the effect of prolonged and intimate contact as being a means of spread; for it must be remembered the doctor *visits* only; he does not stay for a day beside one case as a relative does, nor does he sleep or eat under the same roof as does a nurse. In this way also the immunity of the Chinese students is to be accounted for. They performed their task in a newly-built, commodious, and roomy mat-shed, freely ventilated by being raised three feet from the ground, and its lofty roof constructed so that air swept across between the side walls and the roof, with large apertures in the roof itself, the chance of contracting the disease from so diluted a form was reduced to a minimum.

The practical lesson to be learnt from these statements is that free ventilation and attention to hygienic rules lessen the chance of contracting the disease to a very great extent, not only for Europeans, but also for natives; but that all are liable to contract the disease when, either from the calls of duty or wilful neglect, exposure is extreme.

What has been termed the "MIASMATIC" method of infection bears distinctly upon the maintenance and epidemicity of plague. Miasmatic infection implies a soil-bred disease; a disease existing as we assume malaria does in the earth itself, in the water, or in some particular form of fermenting or decomposing material in which the germ finds a nidus. In a neighborhood so infected, the disease is endemic, as manifested by the fact that again and again the disease recurs; that after a few months of seemingly complete disappearance the disease crops up and runs a more or less severe course.

Rats.—Rats are known to be infected and die of the disease. Moreover, they are a great source of infection indirectly to man by infecting the water supply.

Snakes.—Dr. Thomson remarks in the *British Medical Journal*, September 8th, 1895, page 560: "Moreover, when rats are thus dying, dead snakes also are said to be found about the site in unusual numbers." Later on he remarks: "The snakes eat the rats."

Dogs.—Dr. Mouchard, in the *Chinese Customs' Medical Gazette*, in the forty-seventh and forty-eighth issues, remarks that dogs died during an epidemic of plague. He ascribes it to the dogs eating the flesh of human beings or any other animal dead of plague.

Pigs.—It is even more important to ascertain whether or no the pig is infected. Pork is largely consumed by Chinese; and, moreover, Europeans in the East seldom or never eat Chinese-fed pork. The Chinese died of plague whilst the Europeans enjoyed an immunity from the disease; nothing seems more conclusive than that pork was the infecting food. Moreover, most of the pork brought to the Hong Kong market comes from Pakhoi, a town where plague has been endemic for years.

The first point to be settled is, Does the pig suffer? *Not as a rule.* The pigs from Pakhoi showed no falling off in numbers, and they were not sickly; the former condition would have obtained had plague thinned their numbers in Pakhoi, and the latter would have been found out when they reached Hong Kong, where careful inspection of all food supplies is made.

Dr. Mouchard writes: "We saw on some roads dogs and pigs feeding undisturbed on corpses which no one cared to bury. These animals fell victims to their greed and succumbed to the scourge."

Further, plague has been produced in the pig experimentally, all of which goes to prove that pigs die of plague after consumption of corpses dead from plague and inoculation; but that pigs are not primarily liable to plague in the same way as rats and pigeons, seems conclusively shown.

It will be seen at once that the infection of birds would render the possibility of the rapid spread of contagion and the appearance of the plague in isolated districts easily explicable. It is not comfortable news that we may have a winged distribution of plague.

To sum up our knowledge we find:

1. That the rat is the animal most liable to be attacked.
2. That rats suffering from, or dead of, plague may infect other animals which consume them.
3. That rats are always affected by a disease similar to plague at the same time that man suffers.

INCUBATION.

The time intervening between exposure to and the development of plague is three to six days as the period of incubation, but the evidence within the last few weeks from Calcutta renders the period of incubation of ambulatory plague uncertain.

Invasion.—The onset of the disease in malignant polyadenitis is known to be usually sudden and severe. The patient is seized with headache, fever and prostration, and compelled straightway to seek his bed. In a few hours or a few days a swollen gland develops, and the disease runs its course. But we have on record many cases where high fever existed and the patient did not even feel ill; or where a gland swelled up with no general feverish state. Such cases are sufficient to show that fever or plague may exist and the patient not be aware of it; and the glands may be affected for a fortnight before the disease declares itself in the usual way, by headache, fever and prostration.

The onset of the disease, therefore, even during a plague epidemic, may not be so definite as we should like to believe, and as yet we have no charts recording the condition of the patient between the time of exposure and the invasion.

The Bacillus.—The bacteriology of plague began by the advent of Kitasato from Tokio during the Hong Kong epidemic of 1894. On June 14, 1894, Kitasato demonstrated the bacillus, which was confirmed afterward by Dr. Yersin, of the Pasteur Institute, in Saigon, working in an independent manner. The bacillus has been variously described as (1) a diplococcus; (2) diplococcus enclosed in a delicate capsule; (3) a short bacillus with the ends somewhat rounded and a clear space or band in the center. Professor Woodhead writes: "The size varies considerably according to the staining method employed, the organism appearing rather smaller in the watery gentian-violet solution than in the glycerin-fuchsin solution. It is plain that the size of the capsule and its staining capacity vary very considerably; and it is quite possible that this appearance of a capsule is like that which is sometimes met with around the bacillus of anthrax stained in special solutions in that it may be simply a refraction from the albumin from the constricted bacillus, due to the drying and other processes of preparation." In the figures drawn by Woodhead an organism was met with in some specimens which seems to indicate a development after death. The last statement may be the most important of all, and its confirmation will be anxiously looked for during the present outbreak in India. It may be the first step toward a knowledge of the life-history of the bacillus in the same manner as the flagella of the *plasmodium malariæ* are found to develop in the field of the microscope some half-hour after removal from the body.

THE ACCOMPANIMENTS OF PLAGUE.

Climatic.—The weather does not escape blame for a share in the presence of plague when it rages in the midst of a community. Be it dry, the drought is mentioned as a cause; be it rain, the floods which ensue are held to have damaged the crops, and the grain supply is spoiled, or the miasm resulting from the subsidence of the swollen streams is connected with the outbreak. In Southeast China the epidemic of plague developed at the end of a prolonged and exceptionally dry season. The rainfall was so deficient that most of the wells throughout the district were exhausted, and the crops suffered severely.

Without driving the argument of drought too deeply home, it must, however, be observed that in Bombay we find a similar condition of things before the present outbreak. The rainfall over a wide area of country has been so greatly deficient that wide-spread famine has followed.

Rain.—In Hong Kong it was hoped, in 1894, that, with the advent of rain, the epidemic would abate. The rains delayed their onset until well on in May, by which time the epidemic had got a hold in the town. With the rains came an accession, a marked accession, of the number of plague cases. The flushing of the drains and gutters, the replenishing of the wells with a plentiful supply of water was attended by an increase in the outbreak.

Before referring this positively to the effect of procuring a more moist nidus for the bacillus to develop in, the effect of rain on the habits of the people has to be noticed. In all warm climates a number of the male portion of the inhabitants sleep out of doors, on the roof, in the street, or in verandahs. The effect of rain is to drive all such sleepers within the house, to shut the windows and doors, and to generate all the evils of overcrowding.

Heat and Cold.—In Canton the plague commenced when the temperature averaged about 60° F., and continued when the average daily temperature reached 90°F. Further, it must be noted, that the disease disappeared when heat and moisture were about 90° throughout the district, so that with regard to the common statement that it thrives best at a temperature between 80° and 85° F., it must not be forgotten that, while thriving, it also disappears at the same temperature. It dies out when the conditions which we believe to be suitable for its propagation, heat and moisture, are at their best.

Overcrowding.—The argument of overcrowding might be at once set aside by the sweeping statement that just as plague flourishes in crowded cities so likewise it flourishes in barren deserts where the population is sparse in the extreme. An analogous disease, typhus, behaves in well-nigh the same way, and typhus is looked upon as the direct outcome of overcrowding. Now overcrowding may take place in a country house as readily as in a town house, and the poorer the country the greater the overcrowding. Typhus prevails in isolated houses on the west coast of Galway, Ireland, where the air around is of the purest. But eight or ten people or more in one room, not only sleeping there for warmth, but residing there well-nigh all day when the weather is inclement in winter, will foster any disease that foul air is capable of producing. As with typhus, so with plague.

Poverty.—Plague is ever associated with scarcity and want. Sometimes it is famine caused by the destruction of crops by floods; sometimes by drought; but from whatever cause, plague and scarcity of food are frequently allied. Not only is the grain scarce, but it has often been remarked upon that it is bad, musty, covered may be by blue mold and fermented. The two conditions are to each other as cause and effect. The grain is gathered before it is ripe, owing to the people's necessity, and the unripe grain not only yields insufficient nourishment, but it is apt to undergo fermentation and be attacked by vegetable parasites.

In India, at the present moment, a serious scarcity prevails and famine threatens. The prolonged drought is the cause of failure of crops, and, moreover, the consumption of diseased grain is universal. It may be argued plague exists when famine is unheard of; but the combination which also means overcrowding of houses, must be a factor, if not the chief factor, in the propagation of the disease.

Sanitary Conditions.—The preceding remarks prepare the way for the recognition of possible sanitary evils and neglects as accompaniments of plague.

Chinese towns are at all times ready to generate any filth disease, and Hong Kong itself is but little better. The city was hastily built about fifty years ago, when the sudden inroad of tens of thousands of Chinese sought occupation and habitation under the British rule. From that rush of people and feverish haste to build without proper control, the city never recovered, and to this day presents sanitary aspects of the most flagrant description.

MEDICAL PROGRESS.

The Normal Male Urethra.—JUDASSOHN and DREYSEL report results of their investigations of the normal urethra (*Archiv. f. Dermatol. u. Syph.*, Bd. xxxiv, p. 349). They found the capacity of the anterior urethra to be much greater than it is ordinarily given, depending of course on the power of resistance in the musculus compressor urethræ. With an irrigator held at a height of 80 c.m. the average capacity was found to be 7.8 c.cm.; at 130 cm., 10.65 c.cm.; at 200 cm., 12.9 c.cm. The average quantity which could be injected with a syringe was 11.8 c.cm. The greatest capacity found in any case was 22 c.cm.—a little over 5 drams. It follows from this investigation that in order to accomplish the maximal distension of the urethra, which is so important in gonorrhea, the irrigator should be hung very high.

Of the capacity of the posterior urethra one cannot really speak, for the most minute quantity of fluid injected into it flows at once in the direction of the least resistance, that is, in most cases, into the bladder.

Another interesting point which the authors determined is the reaction of the mucous membrane of the urethra which they found to be constantly alkaline, even after the passage of very acid urine. An occasional exception was found in the fossa navicularis. However as gonococci grow upon both acid and alkaline media this point has no evident practical bearing.

Injuries of the Liver.—The *Rev. de Chirurgie*, October, 1896, contains a complete article upon injuries of the liver, by TERRIER and AUVRAY. The section on diagnosis is well worth repeating. In many cases complicating injuries will obscure the hepatic symptoms so that a diagnosis is impossible, but in many other cases where there is a contusion in the neighborhood of the liver the physician, by carefully locating the pain, can tell whether the injury is simply of the abdominal wall, or extends deeper into the liver itself. If the liver is injured there is a feeling of weight in the right hypochondrium, radiating toward the epigastrium, umbilicus, shoulder, etc. It is a deep pain, not very quick, nor excitable. Pain resulting from a contusion of the abdominal wall is more superficial, and disappears in repose, to recur violently at the least muscular contraction. It is also accompanied by ecchymoses. These may of course be present with injuries of the liver, but not necessarily so.

Besides these local symptoms there are others which are equally valuable in injuries of the liver, such as internal hemorrhage, jaundice, and urine containing sugar, or albumin, or bile. With reference to prognosis, ruptures of the liver, occurring among 750 cases of injury, have hitherto given a mortality of eighty-six per cent., while the mortality for the whole series of injuries was only sixty-four per cent. These figures have recently been much improved by an early exploratory incision and rigid aseptic treatment, so that Terrier and Auvray for their own forty-six cases obtained a mortality of only twenty-eight per cent.

Tuberculosis of the Knee.—The *Gazette Hebdomadaire de Médecine et de Chirurgie* recently contained a review of a work by Koenig upon Tuberculosis of the Knee, which brings out some interesting points concerning this disease. During a period of eighteen years, from 1875 to 1893, Koenig observed and treated 720 cases of tubercular disease of the knee joint—so that his statistics are of considerable value. Of this number 427 were males and 293 females; the right knee was affected 364 times, the left 326, both knees 13, and in 17 cases the location was not noted. In 691 cases the starting point of the disease was observed. In 281 or 44.5 per cent. it began in the bony structure of the joint, and in 351 or 55.5 per cent. the synovial membrane was the primary seat.

Of the bones, the tibia was most frequently involved, *viz.*, 107 times, the femur next, 53 times, the patella 33 times, and in 48 cases all of the bones were affected simultaneously.

The plans of treatment adopted were rest in a proper position, extension, injections of 5 per cent. solutions of carbolic acid, iodoform, glycerin and Koch's tuberculin, and the various operations of arthrectomy, excision and amputation. His conclusions based on this large number of cases are:

1st. That the majority of cases will recover under conservative treatment, but only a few will have a considerable range of motion, and a large proportion will recover with ankylosis in a flexed position.

2d. That no definite prognosis as to the time of cure or the result can be given in the beginning.

3d. That where a case is rebellious, does not improve under conservative treatment, and there is a strong probability of ankylosis in the end, an operation should be done.

Among children arthrectomy is the operation of choice; in adults, excision.

Tuberculosis in other localities is not a contraindication to an operation.

He condemns early amputation in these cases, but also opposes those who wait until the patient has become exhausted by pain and prolonged suppuration.

Menstruation and Conception During Lactation.—REMFRY, by investigation of 900 nursing mothers (*Rev. Intern. de Méd. et de la Chir.*, 1896, No. 5), found that in only 57 per cent. was there absolute amenorrhea. In 20 per cent. menstruation was normal, while 43 per cent. menstruated irregularly. Conception during lactation was also common, especially with the menstruating mothers, *viz.*, 60 per cent. Among those who did not menstruate at all, only 6 per cent. conceived while nursing.

THERAPEUTIC NOTES.

Urethritis: Treatment with Airol.—LEQUEN and LÉVY (*La Presse Médical*, 1896, p. 595) report favorably upon the use of a solution of this remedy as an injection in acute and chronic gonorrheal urethritis.

The remedy, which is a combination of iodid of bismuth and gallic acid, resembles dermatol, but contains more iodid and less bismuth oxid, and is an odorless, tasteless powder, unchanged by light and stable in dry air.

Applied to moist surfaces, it decomposes into its constituent parts, and thus acts as a dessicant and antiseptic.

While insoluble in ordinary media, it forms in the following combination an emulsion which has been used by the writers:

Airol, ...	2 grms.
Glycerin, Aqua dest., } aa. . . .	10 grms.

After washing the urethra with a four-per-cent. aqueous solution of boric acid, an injection is made once daily of 6 cc. of the emulsion.

Treatment for Vertigo.—The following remedy for vertigo, when occurring in arterio-sclerosis, is recommended in the *Rev. de Therapeut. Méd.-Chir.*, November 1, 1896:

Ergotin, ...	10 centi gr.
Extract of Calabor Bran, .	2 "
" " Gentian, . .	q.s.

For a pill. From 1 to 20 are to be taken daily, increasing the dose according to the toleration of the patient.

To Remove Tattoo-marks.—MINIME (*Monatsheft. für pract. Dermatol.*, November 1, 1896) states that in order to remove tattoo-marks the skin is to be washed with a concentrated solution of tannin, pricked with needles. Into the punctures is thrust a sharp-pointed stick of silver nitrate, under considerable pain. Silver tannate is formed in the skin and the tattoo pigment gradually eliminated.

THE MEDICAL NEWS.

A WEEKLY JOURNAL
OF MEDICAL SCIENCE.

COMMUNICATIONS are invited from all parts of the world. Original articles contributed *exclusively* to THE MEDICAL NEWS will after publication be liberally paid for (accounts being rendered quarterly), or 250 reprints will be furnished in place of other remuneration. When necessary to elucidate the text, illustrations will be engraved from drawings or photographs furnished by the author. Manuscripts should be typewritten.

Address the Editor: J. RIDDLE GOFFE, M.D.,
No. 111 FIFTH AVENUE (corner of 18th St.), NEW YORK.

Subscription Price, including postage in U. S. and Canada.

PER ANNUM IN ADVANCE	$4 00
SINGLE COPIES	.10

SATURDAY, JANUARY 23, 1897.

THE PLAGUE IN INDIA.

THE nature and characteristics of the bubonic plague now raging in India are interestingly described in this week's issue of the NEWS by Dr. Cantlie of London, who speaks from personal knowledge and observation. The present outbreak is intensified and made more horrible from the fact that it has appeared in the midst of a widespread famine. The horrors of the situation can with difficulty be imagined. Hundreds are dying daily, and the panic-stricken people are deserting their homes and fleeing from the plague-infected cities. Already a half million are said to have left Bombay. This migration is likely to spread the infection throughout the countries of Western Asia. Add to this process of dissemination the approaching annual pilgrimage to Mecca, and there is presented a combination that becomes appalling.

As a means of propagating disease, these gatherings of pilgrims are the most potent factors known to the civilized world. A few pilgrims infected with cholera germs, by bathing in the sacred pools from which all drink as a sacred rite, have been the means of spreading cholera over remarkably wide regions of country. If to this scourge, which is endemic in the Moslem realms, there be added the destructive forces of the bubonic plague, there will doubtless eventuate a mortality that will surpass all known records. How effectually this may be stamped out or restricted by sanitary enactments and quarantine supervision becomes, therefore, a vital question. At the time of the cholera epidemic in 1894, a system of quarantine was organized by international agreement which proved most efficient and satisfactory in preventing the disease from passing the gateway of the Suez Canal.

This system consisted in establishing quarantine stations at both ends of the Red Sea—one at Camaran to inspect all ships bound to the eastward, and another at Tor, near the entrance of the Suez Canal. At Tor, all ships containing pilgrims from Mecca were obliged to disembark their passengers. These were then arranged in groups, according to their destination, and carefully inspected. Those found sick were placed in hospital, and the members of the group in which they were discovered isolated from the others and kept under prolonged observation. In the meantime, all the passengers were thoroughly bathed, their clothes and luggage subjected to disinfection by heat. The ship was fumigated and scrubbed with germicides. The passengers were then reëmbarked and the vessel allowed to proceed on her journey as far as Suez, where she was again inspected by quarantine authorities, and detained if found infected. To prevent the escape of suspects into the interior during their stay at Tor, a cordon of soldiers was stationed around the entire encampment.

Fortunately, therefore, the international quarantine has this plant established and ready for active and efficient work. Dr. Doty, the Health Officer of New York, has recently returned from a tour of inspection, and he assures us that the system is so complete as to give every certainty of blocking all progress of disease at this point. To make assurance doubly sure, he has inspectors at various points on the Mediterranean to keep him informed of all possible sources of infection. This, with the magnificent quarantine regulation of our ports, allays all possible fear of any invasion along our Atlantic seaboard. As the western limits of this plague are receding in successive outbreaks, and the eastern limits are advancing, it is quite possible that the most imminent danger threatens the Pacific Coast, and quarantine regulations may require serious attention there.

THE SIGNIFICANCE OF RENAL PAIN.

Pain in the neighborhood of the kidney is often very severe, and exists as the chief symptom of many abnormal conditions in this organ. Very often an examination of the urine passed at a time closely associated with the attack will reveal pus, an excess of irritating crystals or other evidence of renal mischief, as blood ; but in other cases the urine gives far less guidance in diagnosis than could be desired. Because of the severity of these pains and because the severity and degree of disease may necessitate operative interference their diagnostic value is great, and it behooves the physician to call to mind, in their presence, their various possible causes. Of course, renal colic due to the passage of a calculus from the pelvis of the kidney through the ureter, will suggest itself as the most probable cause of the attack. The history of previous attacks of a similar character, the radiation of the pain downward into the groin and testicle, or to the end of the penis, aid in deciding that a calculus is passing; while the possible presence of blood in the urine, the irritable bladder and the exquisite agony in the paroxysm, in contrast to the remissions, and the sudden onset still further point to this condition.

These symptoms are not, however, always present in sufficient degree or in association to make the diagnosis easy, and the absence of one prominent sign may seriously impair its certainty. Under these circumstances, the physician at once endeavors to ascertain the other states of the renal neighborhood, and recalls the fact that somewhat similar pains arise from pyelitis with possible nephritic abscess, from neuralgia of the kidney or the tissues near by, from nerve pains due to spinal caries or irritation, and more rarely from tumors adjacent to or in the gland, or from aneurism of vessels, as for example, aneurism of one of the branches of the mesenteric artery. Nor are these all, for, as additional possibilities, a stone or stones imbedded in the renal substance may be found, or excessive deposits of oxalic acid or other crystals, manifesting themselves in gouty kidney, or, finally, cardiac valvular disease, more commonly of the aortic valves; while the aching of the kidney is ascribed to injury, and is most commonly met with in young females who endeavor while wearing corsets to take violent physical exercise.

The presence of pyelitis rarely develops great pain, and the appearances of the urine point clearly to the cause of the discomfort, though if the attacks be sudden in onset the cause may be calculus in the pelvis of the kidney, surrounded by septic changes.

The failure of health and the possible febrile movements and chills still further point to pyelitis. So too, nephritic abscess is accompanied by so much systemic disturbance in many cases as to make the diagnosis clear. The presence of spinal tenderness on pressure or motion in the dorsal or lumbar regions, and the history of spinal irritation or disease, decides this as the cause of the pain; but the discovery of aneurism of any of the abdominal vessels may be impossible, unless it be large enough to manifest itself through the viscera or abdominal wall on palpation. The diagnosis of stone imbedded in the kidney is very difficult and uncertain, but the onset of an attack of renal pain arising from oxaluria or an attack of gout is usually bilateral, and is associated with a scanty urine of high specific gravity, and with much lumbar soreness. A gouty history or that of having eaten large amounts of oxalic acid-bearing foods, such as pears, tomatoes, and cabbage, may be recognized as the predisposing causes of attack.

Nearly forty years ago, Habershon called attention to the fact that aortic valvular disease often caused pain to be radiated into the hypochondrium, and within the last year, Ralfe has, in the Proceedings of the Medical Society of London, detailed the possibility of aching kidney being due to unrecognized trauma. He has met with young women who, by wearing tight corsets while playing tennis or other violent games, have so bruised the right kidney by some sudden and violent movement as to suffer seriously for days afterward. Again, Ralfe asserts that fairly violent renal pain sometimes arises in cases that, by reason of obstinate constipation, have accumulated in the colon hard scybalous masses which, by their pressure, produce reflex irritation and renal agony. As an illustration of the fact that Habershon was correct in stating that valvular disease sometimes causes renal pain, Ralfe asserts that on one occasion no less a person than the late Dr. Murchison called at his house with a specimen of his own urine, voided after an attack of severe renal pain which had come on at night, and which resembled true renal colic so closely that Murchison, who was a sufferer from aortic disease, was confident that he had had renal colic. A reminder from Ralfe of Habershon's statement, and an examination of the urine, soon convinced Murchison of his mistake.

In a similar paper read by Hurry Fenwick before the same society, this gentleman presented additional diagnostic information. He asserts that there are two great groups of renal stones, and that in each class characteristic pain may be felt. In the cortical stones the pain is fixed and continuous, and is liable to exacerbation on movement, but does not depend so much upon changes in the diet. On the other hand, pelvic stones cause obstruction and colic, the pain radiating down into the groin and testicle, while the urine becomes bloody, purulent, or scanty. Of course these cases are not in life divided by any strict line such as we have named ; the more cortical the more characteristic the pain, whereas if lower down there may be the symptoms usually seen when the stone is actually pelvic.

Fenwick also believes that the posture of the patient in bed is typical. In nine out of twelve cases, his patients could sleep only on the affected side. Cortical stones, in his opinion, never cease to give discomfort, but pelvic stones may become imbedded, and the patient go for long periods of time free from any discomfort.

INSANE CONVICTS IN PHILADELPHIA.

It has long been more than a suspicion in the minds of many physicians of Philadelphia that a larger number of insane convicts are incarcerated in the Eastern Penitentiary than is generally supposed. The subject was brought prominently before the public last month by the action of one of the city judges, who appointed a commission to investigate the mental condition of some of these alleged criminal insane. This commission, composed of men of high standing in the professions of medicine and law, has just made a circumstantial and conservative report. The tone of this report is admirable and highly commendable because it shows that the commission as a body carefully avoided the influence of the somewhat sensational literature which the press, and even the inspectors of the penitentiary, and the judge himself, issued upon the question. Much of this literature, including the brilliant polemics between the honorable judge on the one hand and the irate inspectors on the other, unfortunately cannot be noticed here, but the report of the commission, because both of the expert knowledge shown by its members and of the truly judicial tone that characterizes it, presents us with certain lucid aud reliable conclusions.

The method of investigation was direct and searching. The commission in a body, attended by a secretary, went to the convicts in their cells, and made minute and scientific examinations into their mental status. It should be said right here that the commission was not charged with an examination of all the convicts in this immense jail. Under the law of the state it was acting by instruction of a judge of one of the counties only, and had authority only to examine alleged lunatics who had been sentenced from that particular county. As the penitentiary is a state institution, receiving convicts from many counties, the jurisdiction of the commission was too distinctively limited to permit their report to be received as a complete record of the actual number of criminal insane at this time imprisoned within its walls.

The conclusions of the commission are briefly as follows : Of eight alleged insane convicts, the record of whose mental and physical symptoms is given in detail, five should be classed as insane, two as not insane, and one as of doubtful mental state. The five classed as insane and the one of doubtful mental state are proper subjects for treatment in a hospital for the insane. Two of these belong to the dangerous class of insane criminals, and would be best treated in an institution especially provided for the criminal insane. The commission, however, is forced to regret that no such hospital has been provided by the State of Pennsylvania.

This, in a nutshell, is the outcome thus far of what promised in the beginning to be something of a scandal. The findings of the commission are not startling, but they are, or should be, disquieting to the public conscience of the state. Certain practical deductions can be drawn which may help to focus light upon the proper points.

First, we are somewhat disappointed that the commission did not venture an opinion upon the subject of the influence of solitary confinement in causing or promoting insanity. The members of the commission possibly felt that this subject was too large to be based upon the few data which they had obtained. We confess that we do not find much in their report to warrant a dogmatic opinion that solitary confinement engenders insanity. The types of insanity observed by them were evidently the conventional forms of delusional paranoia, with deterioration, which are not uncommon in the criminal insane. This form of insanity is possibly promoted by any system of imprisonment, and until accurate statistics, by expert observers, are made, for comparison, it might be rankly unjust to allege that the cellular system is responsible for more of it than the congregate system. We have heard a most reliable and skilled alienist, of wide observation upon the criminal insane, say that insanity is so closely allied to criminality that it is almost impossible as yet to gauge accurately the effect of imprisonment, of any kind, in its production.

Secondly, the report of the commission seems to imply, although it does not distinctly say, that the authorities of the penitentiary have not been sufficiently alive to their responsibilities under the law of the state. The act of the Assembly of Pennsylvania directs that whenever any person detained in any prison is insane it shall be the duty of the judge of the court under whose order the person is detained, to direct, upon application, an inquiry by commission or otherwise, with notice to the Commission on Lunacy; and if the judge is thus satisfied that such prisoner requires treatment in a hospital for the insane, he shall direct the removal of said prisoner to a state hospital. Now, it is very evident that in such a close corporation as the Eastern Penitentiary such application to a judge lies almost wholly in the discretion of the authorities of the jail. This discretionary power was evidently not properly used in the case of the penitentiary in Philadelphia. To judge from the newspaper literature, and the utterances of the warden and inspectors themselves, these officials have been notoriously ignorant and headstrong in the exercise of their somewhat despotic power. It is even alleged that they do not hesitate to make snap diagnoses of simulated insanity, and to reflect adversely upon the value of expert testimony. These peculiarities have brought upon them a well-deserved share of public criticism, which we hope will awaken in them a sense of their public responsibilities.

Finally, the law of Pennsylvania is evidently radically defective in one essential. It directs that insane prisoners shall be removed from the prisons, but it provides no proper hospital to which to remove them. This defect is clearly pointed out by the judge of Bucks County, one of the contiguous counties to Philadelphia. He, too, appointed a commission in December to report upon the mental state of several prisoners in the Eastern Penitentiary from that county. In his instructions to this commission the learned judge called attention to the grave responsibility of removing dangerous insane criminals from a penitentiary, where they are safely detained, to a state hospital for ordinary non-criminal insane, where they cannot be safely kept. He wisely says that it is a serious question whether it is safe, wise, or proper, to commit such criminal lunatics to a hospital in which they must be detained along with the innocent. This criticism, of course, points to but one remedy — the establishment in Pennsylvania of a special hospital for the criminal insane. In this respect Pennsylvania is still backward, although not more so than many other states, but by reason of her wealth and greatness her defect is more conspicuous. We confess that we do not see what good result can come from the present agitation, unless it be the establishment of such a hospital. We believe that such will ultimately be the result, and that too much credit cannot be given to the humane judge and the enlightened and conscientious members of the commission who have taken the initiative in this important step.

ECHOES AND NEWS.

Expert Witnesses.—The Minnesota Medical Association is agitating the question of legalized expert witnesses.

Sir Joseph Lister's Peerage a Life One Only.—Sir Joseph has no direct male descendant. Lady Lister, who was a daughter of the late Mr. Syme, of Edinburgh, died a few years ago without any issue.

Prizes of the Academie des Sciences.—At the annual public meeting held in Paris, December 21, 1896, the Montyon prize of $15,000 was divided among Professor S. Laskowski, of Geneva (Atlas of Human Anatomy); M. Legrain (Researches on Alcoholism), and MM. Imbert and Bertin-Sans, of Montpelier, and Oudin and Barthilomy, of Paris (Application of Skiagraphy to Medical Science).

Portrait of Mr. Herbert Spencer.—In response to a letter signed by a large number of eminent Englishmen, Mr. Spencer has consented to allow his portrait to be painted and presented to the nation.

Resignation of Professor Chandler.—Prof. Charles F. Chandler has retired from the Professorship of Chemistry and Medical Jurisprudence in the College of Physicians and Surgeons, but retains the Professorship of Chemistry in Columbia University.

The Telephone in Practice,—A young physician of Illinois has built a private telephone line connecting his office with the residences of all his country patients. When he is older, we predict that his love for the insistent jingle of the telephone-bell will be less ardent.

Appendicitis on the Left Side.—In the case of a lad who recently died in Danbury, Conn., the usual symptoms of appendicular disease were present, but all signs were referred to the left side of the abdomen. An autopsy revealed the anomaly of a more or less complete transposition of all of the viscera and a general septic peritonitis the result of perforation.

A Woman as Presiding Officer in the British Medical Association.—The East Anglian Branch of the British Medical Association has placed Mrs. Garret Anderson in its Presidential chair. The triumphant march of women doctors into the ranks and official positions of this association has been steady and determined, and the end is not yet.

Pasteur Institutes in Russia.—There are seven institutes in Russia in active operation for the treatment of hydrophobia. The total number of patients treated between 1886 and 1892 was 14,369, of whom 265, or 1.84 per cent. died. More than 9,000 of these were bitten by dogs, and of these, 0.79 per cent. died, while 621 were bitten by wolves, and of these 16.26 per cent. died.

Total Extirpation of the Bladder.—On the 5th of this month Dr. Tuffler presented a man before the Academy of Medicine, Paris, from whom, on October 10th, he had performed complete exeresis. The patient suffered from a diffuse tumor of the bladder. By the use of a tube-syphon and hypogastric receptacle for the urine, he was thus able to return to his work much improved in his general health.

One Million Dollars for a Hospital.—Mr. J. Pierpont Morgan has offered to build a new home for the New York Lying-in Hospital at Seventeenth street and Second Avenue. He is ready to donate $1,000,000 for this purpose as soon as the management can show an endowment sufficient to carry on the work of the hospital. Mr. Duer, president of the Board of Governors, is confident that no difficulty will be found in complying with the terms of Mr. Morgan's offer.

Board of Surgeons for Brooklyn.—A bill has been introduced in the Assembly at Albany providing that after May 1, 1897, there shall be a Board of Physicians and Surgeons in Brooklyn, to be appointed by the Mayor, to perform the services now performed by the surgeons connected with the city department. The board is to consist of a chairman and nine competent physicians and surgeons. The chairman is to receive a salary of $2,500 and the other members $2,000 each.

The Pennsylvania Society for the Prevention of Tuberculosis.—It is proposed by the members of this organization to build a sanitarium for the treatment of consumptives upon the Blue Ridge slope in Luzerne county, Penn. A tract of six hundred acres of land near Glen Summit has been acquired and upon this one of five pavilions will be erected as soon as the sum of $15,000 has been raised by private subscription. A bill will be introduced asking the State Legislature to appropriate $100,000 every second year toward the enterprise.

The Use of the Incubator.—Dr. L. Fürst, of Leipzig, says that in April, 1890, he induced labor at six months and one week in a lady suffering from edema of legs and face, her urine containing sufficient albumin to make it solid on boiling. She escaped eclampsia and recovered completely. The infant, a girl, weighed, when born, between two and three pounds. She was at once placed in one of Hearson's Thermostatic Nurses (an incubator), and was thus reared, and she is now a remarkably fine and intelligent child for her age.

Dr. Abbott in the Philadelphia Board of Health.—Director Riter has named Dr. A. C. Abbott, of the Laboratory of Hygiene, University of Pennsylvania, as chief of the bacteriological division of the Philadelphia Bureau of Health, in place of Dr. B. Meade Bolton, resigned. Dr. Abbott's contributions to scientific literature have been numerous, among the more prominent being "The Relation Between Water Supplies and Epidemics," "Typhoid Fever in Lower Animals," "Report on the Koch Treatment of Tuberculosis at Berlin," he having been sent as a representative of the Johns Hopkins Hospital to Berlin to obtain the materials for this report; "The Etiology of Diphtheria" and "The Principles of Bacteriology," a text book now in its third edition.

The Fire at Bellevue Hospital Medical College.—A fire broke out early Wednesday morning, January 20th, in the rear of the upper story of the College building. The origin of it is attributed to the electric light wire. The dissecting room was entirely destroyed, as well as the story below, and the entire building flooded with water. The records of the College were saved and the contents of the chemical and physiological laboratories escaped serious damage. Fortunately most of the dissecting work had been completed by the members of the graduating class. The regular lectures were continued without interruption at the Carnegie Laboratory and the ampitheater of Bellevue Hospital. The unusually large class of students that is in attendance this year will therefore not be seriously inconvenienced. It is expected that the building will be promptly restored and enlarged.

Advertising by Medical Men.—*The Medical Press and Circular* says: "Within recent years, and more especially of late, a particularly pernicious form of advertising has arisen. We allude to the custom of forwarding purely medical works for review to lay newspapers. From Fellows and even officers of the Royal College of Physicians, this special unethical procedure has apparently met with no remonstrance. Of course, the authors will probably reply that they have nothing to do with any arrangements which their publishers might make in the interests of the sale of the work. But most persons are now aware that an excuse of this sort has no foundation in fact. It would only be necessary for an author to intimate to his publisher the desire that no copies of his book should be sent for review outside of the ordinary professional channels, and it cannot be doubted for a moment that the wish would be attended to and carried out."

CORRESPONDENCE.

A CASE OF VIRGINAL GONORRHEAL VAGINITIS.

To the Editor of THE MEDICAL NEWS.

DEAR SIR: A. B., æt. twenty-one, school-teacher, evidently of an investigating turn of mind, consulted me in November last concerning a violent itching in her genitalia, which had been growing worse for a week past, and was now unbearable.

Examination, which was submitted to most reluctantly, revealed the mucous membrane of the vulva and hymen red, swollen, and covered with a thick whitish mucous discharge, a specimen of which, when mounted and stained, revealed under the microscope gonococci in abundance.

The hymen was intact, and barely permitted the insertion of my finger. The vagina was hot, swollen, tender, and bathed in abundant mucous discharge, showing a deep-seated infection; on irrigation, great flakes of white mucous discharge were washed out.

She was informed of her condition and put on the usual treatment.

She denied any improprieties whatever, and said, among other things, in answer to my inquiries, that two weeks before, while visiting a friend, she saw her syringe, and became possessed with a desire to use it, never having seen or used one before, "just to see how the thing worked."

Her friend instructed her in the art of using the instrument, although she had been using it for some time past with a solution of "acetate of lead and alum." This friendly instruction would seem to account for the infection.

The above may be of interest on account of the peculiarity of the manner of infection.

Yours truly,
LEEDOM SHARP, M.D.

1335 PINE STREET,
Philadelphia, December 29, 1896.

A CASE OF MUCO-MEMBRANOUS ENTERITIS, WITH DEPOSIT OF INTESTINAL SAND.

To the Editor of THE MEDICAL NEWS.

DEAR SIR: In THE MEDICAL NEWS of August 29, 1896, under "Medical Progress," appeared a description of two cases of "intestinal sand and muco-membranous enteritis," reported first by Mathieu and Richard (*Gaz. hebdom. de Méd. et de Chirurg.*, May 28, 1896).

Since reading this report I have had a similar case in my practice. The woman, æt. thirty-four years, gives a history of having had a pelvic abscess seven years ago, which finally ruptured into the bowel, and has continued discharging intermittently and in diminishing quantities ever since. On dilating the sphincter ani a small quantity of pus almost invariably escapes. This pus was examined by a bacteriologist and found to contain only staphylococci.

The patient has suffered from a chronic muco-membranous enteritis for the past five years, with alternating diarrhea and constipation. About one year ago she first noticed the passage of quantities of small sand-like masses, which she likened to grains of pepper. These masses were freely soluble in nitric acid, and under the microscope were found to consist principally of phosphate of lime, both crystalline and amorphous. The probable sequence of events in this case was as follows: The continued passage of acrid pus over the intestinal mucous membrane gave rise to inflammatory changes in it and in the glandular structures, which resulted in the development of muco-enteritis, and the muco-enteritis, in its turn, seems to be the cause of the production of the lime-salts.

The exact mode of production of these lime-salts is not well understood, but it is possible that they may be a pathological product of the mucous glands of the intestine, just as it is supposed that the greater portion of the lime-salts that enter into the formation of gall-stones are a pathological product of the mucous glands of the gall-bladder.

Yours respectfully,
ELEANOR C. JONES, M.D.

PHILADELPHIA,
December 15, 1896.

A RAPID METHOD OF FILTERING.

To the Editor of THE MEDICAL NEWS.

DEAR SIR: In THE MEDICAL NEWS of March 21, 1896, p. 325, was an article by Dr. Friend of Milwaukee, entitled "A Rapid Method of Filtering." I have recently discovered a method which I believe to be new and decidedly more rapid and convenient than the one mentioned.

Take a pledget of absorbent cotton large enough to fill the lumen of a test-tube tightly and tie a long thread to the middle of it. Then force it to the *bottom* of the tube in such position that the thread, when drawn on, shall pull from the bottom of the pledget, thereby tending to expand instead of to contract it. Now fill the tube with the fluid to be filtered, and as soon as the cotton is saturated and bubbles cease to rise from it, withdraw the cotton steadily by the thread. The cotton forms a piston of which the fluid is the valve and the thread is the rod. In withdrawing it a vacuum is formed, into which the fluid is forced. One can scarcely withdraw the pledget quickly enough to spill the fluid. Its advantages over the other methods are greater rapidity, no heating and cooling (so no liability of breaking test-tubes), and the ability to practically fill the tube with one manipulation.

Yours truly,
D. R. BOWEN, M.D.

WELLSBURG, N. Y.,
December 28, 1896.

OUR PHILADELPHIA LETTER.

[From our Special Correspondent.]

MEETINGS OF THE PHILADELPHIA PEDIATRIC SOCIETY, THE PHILADELPHIA COUNTY MEDICAL SOCIETY, AND THE PATHOLOGICAL SOCIETY OF PHILADELPHIA—DIVISION OF THE CHAIR OF ANATOMY AND CLINICAL SURGERY AT THE MEDICO-CHIRURGICAL COLLEGE—MEETING OF THE ALUMNI ASSOCIATION OF JEFFERSON COLLEGE.

January 17, 1897.

AT the first regular meeting of the Philadelphia Pediatric Society, held on January 12th, Dr. F. A. Packard presented a case of dilatation of the stomach. Dr. Alfred Stengel exhibited a case of chorea with arsenical neuritis. The patient—a boy about twelve years of age—had been given Fowler's solution of arsenic in ascending doses for the chorea, and was taking ten minims three times daily when the neuritis developed. All of the classical symptoms of neuritis could not be shown, yet those elicited confirmed this diagnosis to a greater extent than any other that could be advanced in the discussion of the case. An interesting and rare case of progressive neural atrophy was shown by Dr. C. S. Potts. The type was of the peroneal form described by Charcot and Tooth, the atrophy beginning in the muscles of the legs, with associated reactions of degeneration, and contractures. Three cases of cretinism were presented, one by Dr. H. B. Carpenter and two by Dr. H. M. Fussell. All of the patients were under twelve years of age, and were in no way related. Nothing new in the etiology of this condition was adduced, the point of especial interest being the marked improvement in all of the cases, both mentally and physically, under the administration of thyroid extract. A paper by Dr. George Woodward, on "The Chemistry of Colostrum Milk" proved to be a valuable addition to the scanty literature on this subject.

At a stated meeting of the Philadelphia County Medical Society, held on January 13th, an electrical headlight, the invention of Dr. Nephews of Chicago, was shown, which, from its efficiency and simplicity, should prove eminently satisfactory. The points in its favor are that, by an ingenious attachment, the current employed in the ordinary incandescent lamp system can be used, and that a switch on the headband of the apparatus accurately controls the current. Another lamp for use in the nasal cavity, or in other locations where light without heat is required, is so arranged that a continuous stream of water flows around it without interfering with the light, yet so controlling the radiation of heat that the illumination can be employed as long as desired without fear of injuring the surrounding parts. Dr. Thomas S. K. Morton exhibited a patient from whom he had removed the head of the right radius. The history of the case, when it came under his care, was that both bones of the forearm had been accidentally broken, but good union had been obtained, with, however, a neuritis of the parts and restriction of motion, which proved to be due to a forward dislocation of the radius at its head. Excision of this part of the bone down to the insertion of the biceps muscle completely restored all of its functions to the part. A case of extensive and entirely successful skin-grafting by Thiersch's method was also shown by Dr. Morton. Dr. J. P. Mann read a paper on the "Treatment of Club-foot," dividing the treatment of this condition into (1) mechanical and (2) mechanical and operating. Dr. Mann expressed himself as being essentially opposed to the removal of bone for the correction of the deformity, and stated that the employment of suitable apparatus after subcutaneous operation would accomplish equally good, if not better, results, except in the rarest of cases. Discussion of the paper by Drs. Willard, Young, Morton, and Davis agreed in the main with Dr. Mann's views, except that a larger field was conceded to the open operation than that granted by the author.

At a stated meeting of the Pathological Society, held on January 14th, Dr. D. J. McCarthy showed the specimen from a case of ruptured aneurism of the celiac axis. An interesting paper was read by Dr. J. Dutton Steele, on "The Distribution and Etiology of Cardiac Hydrothorax." Having noticed in a nun ber of cases of hydrothorax of cardiac origin, observed clinically and collected from *post-mortem* records, that the effusion, if bilateral, was generally greater on the right side, and that if one pleura alone were the seat of the transudation, it was also, as a rule, the right, Dr. Steele had endeavored to find a solution for this (at least) singular coincidence. Eliminating all other causes for edema except the heart, he found that the right auricle, from its anatomical position in front of the root of the lung and the azygos vein, if enlarged, would interfere with the return circulation from the pleura on that side, and also that this is the chamber of the heart first to enlarge in cardiac weakness. The left auricle, if distended, will also produce a like result in the left pleura, but less frequently, on account of its physiological relation to the circulation.

The Board of Trustees of the Medico-Chirurgical College, at a meeting held on January 11th, decided to divide the chair of General, Descriptive, and Surgical Anatomy and Clinical Surgery held by the late Professor William H. Pancoast into two independent chairs of Anatomy and Surgery. It is a matter of much speculative interest as to who will be appointed to these positions.

The Alumni Association of Jefferson Medical College held its annual meeting on the evening of January 16th and elected officers for the ensuing year. Dr. N. G. McCormick of Williamsport, Pa., was chosen president. Among the vice-presidents may be mentioned Dr. Thomas

Addis Emmett, of New York, and Drs. W. H. Warner, John Strobel, I. P. Strettmater, and George McClellan, of Philadelphia.

THE INDICATIONS FOR VENESECTION—SUPPURATION IN THE NASAL CAVITIES A CAUSE OF MENINGITIS—PNEUMOCOCCI IN THE BLOOD OF PNEUMONIA PATIENTS—THE VIRULENCE OF PUS IN PELVIC SUPPURATIONS.

At the meeting of the Medical Society, November 25, 1896, the subject of *venesection* was discussed. EWALD said that he had never entirely given up its use. In the last ten years he had treated 111 cases of nephritis, 18 of which had uremic symptoms. Seven of these were treated by venesection. In four of them the result was prompt and satisfactory, but in three others no good results followed. Unfortunately, it is impossible to foretell which cases would be benefited. Very little is known about the physiologic effects following venesection. One can only say that the amount of blood withdrawn will very quickly be replaced from the lymph vessels. We know, further, that the blood pressure is affected only for a moment. In order to lower its tension for a considerable time it is necessary to withdraw a very large quantity of blood—many times as much as would be advisable in venesection. Ewald's opinion was that, in general, venesection is not practised as much as is desirable.

ALBU had seen the convulsions of uremia and epilepsy cut short by opening a vein. The same was true of carbonic-acid intoxication due to disease of the lungs or heart. In these cases no other treatment is capable of producing such swift and sure results. In pneumonia the time to practise venesection is at the height of the disease, just before the crisis, and before the paralysis of the heart has proceeded too far.

LANDAU confirmed the good results attributed to venesection in eclampsia.

SENATOR thought that venesection was indicated in most apoplectic attacks. He regretted that the indications for its use in this and other diseases were not better understood.

GRAWITZ called attention to the great increase in the number of leucocytes which follows hemorrhage. The blood also shows an increased quantity of sugar and a diminished alkalinity. A person who has lost blood usually perspires freely, and sometimes has fever, so that the reaction of the entire body which follows the loss of blood may well explain the good results which have been attributed to venesection.

At the session of December 2, 1896, TREITEL read a paper on the *diseases of the brain which follow suppuration in the nasal cavities.* This cause is not so important as that of inflammation in the ear. Thus, in 6000 autopsies there were 21 cases of brain abscess, 7 of which were secondary to trouble in the ear, while only 3 were derived from the nose. When one considers the intimate relations between the nasal and cranial cavities, it is rather surprising that infection by this route so seldom occurs. The veins, and probably the lymph vessels also, are directly connected through the cribriform plate with the sinuses of the skull. Besides this, there is the possibility of infection by contiguity. From a clinical point of view, several cases have been recorded in which the same coccus was found in the meninges and in the nasal cavities, and the cavities connected with them. In some of these the relation of cause and effect was clearly proved. In about one-third of them the abscess was extradural, while nearly one-half were abscesses of the brain itself.

Suppuration in the frontal sinuses is of practical interest both on account of its relative frequency and because it is easily accessible. Further, suppuration within the skull, if secondary to that of the frontal sinuses, is usually localized, and is naturally more easily reached than that, for instance, of the cavernous sinus.

SILEX reported a case of abscess of the frontal sinus, which was opened and a very foul pus evacuated. Irrigation and drainage relieved the pain and fever, but on the sixth day these symptoms recurred without evident cause, and three days later the patient died. Nearly the whole upper surface of the brain was covered with thick pus. In the brain substance were two small abscesses. The source of infection in this case was a carious molar tooth which produced suppuration of the antrum of Highmore, the frontal sinuses, and the ethmoidal cells. Such cases Silex considered to be far commoner in the eye-classes of a dispensary than is usually supposed.

At the session of the Union for Internal Medicine, held December 7, 1896, KOHN reported the results of the *examination of the blood in pneumonia.* By puncture of a vein in the arm, blood was obtained and examined bacteriologically. In twenty-three cases the result was negative. Eighteen of these patients recovered and five died, two from a staphylococcus-empyema. In nine instances pneumococci developed in the cultures from the blood. Seven of these patients died. Only two of them recovered after having developed pyemia with metastatic abscesses in one case, and empyema in the other. These were all cases of acute pneumonia. From these results it is evident that the presence of pneumococci in the blood of pneumonia patients renders the prognosis exceedingly unfavorable. This complication of the disease is properly spoken of as a pneumococcus sepsis, which is to be looked upon as a possible cause of death, in addition to those causes already recognized. The presence of pneumococci in the blood may result from the diminished power of the resistance of the body, equally as well as from the increased virulence of the bacteria. The bacteria were found in the blood from twenty-four to forty-eight hours before death. The treatment indicated was diaphoretic and diuretic, in order to facilitate the expulsion of the bacteria.

VON LEYDEN agreed in the main with Kohn, but did not think that this was a definite form of sepsis, as the cases in which pneumococci were found in the blood did not present a special clinical picture.

At the meeting of the Society for Obstetrics and Gynecology, held November 13, 1896, KIEFER discussed the *virulence of the pus in suppuration of the adnexa.* In forty cases in which the peritoneum was soiled with pus at operation, the virulence of the pus must have been slight, as not one of the patients died from infection. The reason of this Kiefer considered to be the thick adhesions which rapidly form in the pelvis around suppurative foci. As a result the bacteria die out in the course of six months or a year, by reason of the over-production of their own toxins. During this time, therefore, extirpation is still indicated, while massage should be avoided. In abscess cavities which communicate with the vagina or intestine, the virulence of the germs may be kept up much longer.

MARTIN presented sections through the pelvis of a woman who died from heart disease with a moderate amount of ascites. From these sections it was shown that the ovary occupies a position just in front of the sacro-iliac synchondrosis. Its long axis is parallel to the long axis of the body. Its base is directed forward and a little outward, its free margin backward and inward. Other members of the Society who were present did not entirely agree with these conclusions.

SOCIETY PROCEEDINGS.

PHILADELPHIA COUNTY MEDICAL SOCIETY.

Stated Meeting, December 9, 1896.

The President, DR. J. C. WILSON, in the chair.

EDWARD MARTIN, M.D., made a communication upon the

AMBULANT TREATMENT OF FRACTURES OF THE LEGS,

and demonstrated the method of applying the dressing, also exhibiting patients. By this means the patient, instead of being confined to bed for five or six weeks, can get about and attend to light duties. The treatment has been employed by Dr. Martin in upward of thirty cases, twelve within the past six or eight months, and the results in almost all have been good. In two the results were not thoroughly satisfactory, but in these the dressing was not applied by Dr. Martin personally. One of these was a case of Pott's fracture. The deformity, however, was not greater than is often noticed after other forms of treatment, but there should have been none. The other case was one of compound fracture, with marked shortening. Five cases were shown in which the treatment had been employed, and in all union appeared admirable, without obvious deformity.

Dr. Martin explained that he was not advocating this method of dressing particularly, nor was he endeavoring to prove that it was better than any other. He merely wished to decide what its real merits are, and he was simply taking testimony. The principle on which the dressing is based is that of fixation and shifting of support. Where one or both bones of the leg are broken, there is a tendency to overlapping of the bones when the weight is thrown upon the foot. If the weight of the body can be carried from above the fracture to the ground by external support, as by means of a plaster cast passing from the knee-joint to below the sole of the foot, the tendency to overlapping will be at once corrected. If, at the same time, the weight of the body can be kept from causing over-riding of the fragments, and the fragments be fixed in good position, there seems to be no good reason why the patient should not use his leg. In the ambulant splint this end is attained by so applying the plaster that the weight of the body is carried from the tibial tuberosities, just below the knee, to the reinforced portion of the dressing lying below the sole of the foot, pressure upon the malleoli being avoided by abundant cotton padding. By this means both of the joints contiguous to the fracture are fixed.

The dressing may be open to the objection that it prevents massage. It is inapplicable when there is great swelling, and when the shape of the legs is such that the weight cannot be carried from the tibial tuberosities to the rigid dressing that envelops the leg, as in fat women with small bones. The dressing should be applied as early as possible. It requires abundant padding with some elastic material. It must be so applied that the plaster does not press against the malleoli, and the plaster must be neatly fitted below the knee. It should be worn for from four to six weeks.

On the day following the application of the dressing the patient should be gotten out of bed and made to walk with the aid of an attendant, who supports him under the arm. In a day or two walking becomes possible with two crutches, in another day with one crutch, and in a week the patient can usually get along with a cane, or without any support. The dressing has the further advantage that it is attended with less atrophy than attends other modes of treatment. The plaster employed should be fresh and should be incorporated into gauze of a coarser mesh than that ordinarily employed.

After the fracture has been reduced, under an anesthetic if necessary, a flannel roller is applied. Cotton batting is next wrapped around the member and the plaster is applied. To flange out the lower part of the plaster and to give a little more strength to the dressing, slightly flexible steel rods, molded to the shape of the leg, are applied upon the sides. The toes should point upward, so as to avoid striking objects in moving about, and the heel should be a little lower than the toes. The malleoli should be thickly padded to avoid compression by the plaster. When the plaster is designed to bear pressure at the knee-joint the batting should be thinner there. To facilitate the cutting of the plaster when it is to be removed, a strip of lead may be incorporated in the dressing. The sole of the foot is padded with a mass of cotton at least three inches thick. The plaster bandage is applied with more firmness than usual, on account of the thick layer of batting. If the patient has been anesthetized the narcosis should be maintained until the dressing has become hardened. Twenty-four hours after the dressing has been applied the patient is permitted to put the foot to the ground.

DR. ERNEST LAPLACE spoke in favor of the mode of treatment, especially in cases in which it is desirable that the patient should not be confined to bed and to the house. It has the further advantage of diminishing the danger of deformity or of imperfect union from contraction of irritated muscles.

DR. **OSCAR H. ALLIS** said that the oldest treatment on record, and one that has never been reversed, demands, first, replacement of the fragments, and secondly, their immobilization. As has been shown, these results can be secured equally with an ambulant dressing as with the fracture-box. Dr. Allis called attention to the possibility of medico-legal trouble from deformity or failure to unite in cases treated with the ambulant dressing. He further pointed out that placing the foot at right angles with the leg may result, through muscular action, in overlapping of the fragments.

DR. **J. M. BARTON** said that he had employed the ambulant method of treatment in several cases, with satisfactory results. As some patients are rendered uncomfortable by having the foot placed at right angles with the leg the heel may be very thickly padded, in order that some support may be received at this point.

DR. **G. G. DAVIS** stated that in most cases of fracture the results are directly proportionate to the amount of care expended upon them. He expressed a fear that in a difficult case the ambulant treatment would not be as efficacious as other means. He thought it would be better to defer its employment until eight or ten days after the fracture has occurred. He held that the treatment of fractures with plaster-of-Paris yields unsatisfactory results in unskilled hands, and is an untrustworthy dressing to use from the first. Displacements may take place beneath the dressing and remain undiscovered until its removal. The field for ambulatory dressings for fractures is limited. They are not at all applicable to fractures of the thigh. As a rule, not much harm results from the detention in bed necessary during the treatment of fractures of the leg by ordinary means, but when such detention is objectionable from any cause, the ambulant dressing should prove of great service. This result may be attained also by the use of a high shoe on the opposite foot and crutches, the leg being made immobile by a dressing of sodium silicate or other means. The same object may be effected by the use of a Thomas knee-splint, in which the support is taken upon the ischial tuberosities by parallel bars along the side of the leg.

Dr. **J. P. MANN** stated that he had used the ambulatory method of treating fractures on several occasions, but he was not convinced that it is the best method. He pointed out that there was some bowing in at least two of the cases shown, although this might have been present before, and it was not greater than is often seen after treatment by other means. In the treatment of such fractures the usual plaster-of-Paris splint is preferable, as during its application extension and proper apposition of the parts can be maintained. Thus, in a case of compound fracture of the tibia, a section of plaster dressing can be placed above the site of injury and another below and the two connected by strips of iron in turn bound in by plaster. If considerable swelling exist the limb can first be enveloped in cotton before the plaster is applied; when the swelling has subsided a firmer dressing can be substituted.

THOS. J. MAYS, M.D., read a paper on

THE LOCAL APPLICATION OF COLD IN ACUTE PNEUMONIA,

being the third collective report, with a discussion of fever in this disease. He presented a tabulated report of 104 cases of pneumonia treated by means of cold applications, in addition to 195 previously reported. Of ninety-four in which the sex was mentioned, sixty-three were in males, thirty-one in females. The patients varied in age from less than one year to between seventy-five and eighty. The highest temperature reached in any of the seventy cases in which this was noted was 106°F. The highest respiratory frequency in any of forty-seven cases was 50. The crisis in fifty-two cases took place between the second and tenth days. In seventy-six cases one lung was involved, in fifteen both lungs. Among the 104 cases there were three deaths—a mortality of 2.88 per cent. Among the total number of 299 there were ten deaths—a mortality of 3.35 per cent.

Dr. Mays considered at length the subject of fever and acute pneumonia in their relation to cold applied externally. He pointed out that the heat of the body is generated almost exclusively through oxidation, principally taking place in the muscles. Coincidentally there is a certain amount of heat-dissipation in a variety of ways. The temperature of the body will depend upon the relation that exists between these two processes, and it is maintained almost constant and uniform through the agency of a specialized nervous apparatus known as the thermotaxic mechanism. When the functions of this apparatus become deranged heat-production or heat-dissipation, or both, become disordered, and fever, or hyperpyrexia, or in some instances subnormal temperature results. In the lower forms of life, as in the molluscs and reptiles, the thermotaxic mechanism is but poorly developed, and the bodily temperature is largely dependent upon that of the surroundings, as is also that of warm-blooded animals poisoned with curare. In the first days of extra-uterine life the temperature of the body is subjected to wide variations, because at this time the thermotaxic mechanism is especially unstable. It has been shown that there exist in man six heat-regulating centers—two in the cortex and four at the base of the brain. Electric or mechanical irritation of these centers is attended with a rise of temperature lasting for hours at a time. Fever may therefore be looked upon as a neurosis, due to the disturbance of the thermotaxic mechanism, and not as a healthy reaction of the organism against the cause of disease. It is an indication that the function of heat-coördination is disordered, and is *per se* a morbid process. It has further been shown that the blood of animals dead from the effects of artificial fever contains a poison that causes convulsions, stupor, and death in guinea-pigs, sparrows, and frogs. The heat-centers at the base of the brain are in close anatomic relation with the respiratory center, and the rapid respiration that attends febrile states is due to irritation of this center. There is reason for believing that the pneumonic process itself is in a great measure dependent upon serious disturbance of the nervous system in which the respiratory nerves and center participate very largely, and hence the increased frequency of breathing in this disease may be due partly to central and partly to reflex influences. The close anatomic relation of the several centers at the base of the brain may explain the frequency of respiration, the high fever and the convulsions that attend inflammatory disorders implicating the base of the brain, *e.g.*, pneumonia and cerebro-spinal meningitis, especially in young children. The foregoing considerations suggest the following therapeutic indications: (1) an abatement of the local process in the lungs; (2) a reduction of fever; and (3) an alleviation of cerebral and general nervous irritation. These indications will be more satisfactorily met by the use of cold applied externally than by any other measure. Not only will cold allay the morbid process in the lungs, but it exerts a direct ameliorating influence on the nerve-centers that play so important a part in the pathology of pneumonia.

The effects of cold applications to the chest are twofold: The cold limits and checks the extension of the pneumonic process and aids in bringing about resolution; by its influence upon the respiratory and the peripheral nerves of the thorax it has a profound sedative influence upon the heart, the respiratory, and the polypneic centers. Respiration and pulse are reduced in frequency; fever abates, the temperature sometimes falling several degrees in a very short time; crisis is hastened; and if the attack is not aborted its duration is materially shortened.

Cold applied to the head acts directly on the brain. Such applications should always be made when there is high fever, great restlessness, and general irritability, and they are not out of place in less severe cases.

The cold may be applied in the form of ice contained in rubber bags, or snow in rubber bags or wrapped up in towels, or towels wrung out in cold water. The bags may be wrapped in towels, applied over the inflamed area in the lung, and held in place with bandages. If the disease is confined to the anterior portion of the base of one lung, a single large bag will suffice, but if the exudation is more extensive, or lateral, or posterior, one or two more bags will be required.

The period during which the applications should be continued will be determined by the degree of fever present. If the temperature falls to the normal, or below, and remains there, the cold may be gradually removed. Too great haste, however, should not be made in the removal, for when the temperature rises subsequently it is less easy to reduce. It must be borne in mind that the applications are made not only to reduce temperature, but also to prevent extension of the morbid process in the lungs.

DR. JAS. TYSON stated that his personal experience in the treatment of pneumonia with cold had been so satisfactory that he had concluded to treat all cases of this disease presenting high temperature in this way. It is likely that this employment of cold is serviceable exactly as it is in the treatment of typhoid fever, while the high temperature, being less protracted, is less dangerous. There need be no fear of harm coming to the patient from the cold, however applied, so long as the fever lasts, but the application should be discontinued as soon as the temperature approaches the normal. It is well not to use cold in cases, especially in old persons and alcoholics, in which there is no elevation of temperature.

DR. JAS. M. ANDERS said that he had employed cold in the treatment of some eight cases of pneumonia, with good effects in all. In none was the disease aborted, but the general course of the attack seemed to be somewhat milder than under other methods of treatment. Cold is, however, not to be employed as a routine measure in this way; nor is it applicable to all cases of acute pneumonia. The cases should be selected. Neither infants nor old persons, nor those debilitated, or with markedly sensitive organizations, are suitable subjects. In some cases the application of cold will do harm rather than good. It is especially in the first stage of the disease that cold is useful in the treatment of pneumonia.

DR. H. A. HARE said that after the stage of congestion had passed and the second stage entered upon, indications must be met and combated as they arise. A temperature of 103° or 104° F. that lasts for only a day or two exerts no particularly deleterious influence, but when hyperpyrexia is reached heatstroke must be considered. It is not likely that cold applied to the chest does more than reduce the temperature. In the early stage of pneumonia the relief of congestion by appropriate measures should be attempted, but if the lung is choked up with exudate, the cold can be of little service. When the stage of consolidation has developed the continuous application of cold could not be hoped to expedite resolution and absorption; and great care must be exercised in the treatment of cases of pneumonia in which, on account of inherent feebleness or delicacy of the system, cold is contraindicated. The continued application of cold to the chest up to the occurrence of crisis may result in a sudden decline in the temperature, with the patient in collapse.

DR. S. SOLIS-COHEN said that if statistics could be relied upon to prove anything as to the treatment of a disease by a special method, the statistics presented would at first sight seem to prove the contention that cold had a special influence upon the pneumonic process; but cases of both catarrhal and croupous pneumonia differ so much in origin and in course, as well as in the complications with which they may be attended, in the age and constitution of the patient, and in the time and circumstances under which they are manifested, that it would be utterly impossible for any one plan of treatment to answer in every case. On the other hand, the statistics of Fenwick, from the London Hospital, including a thousand cases of acute lobar pneumonia, show clearly the usefulness of fever and of fever-heat as Nature's method of bringing about recovery. From these statistics it appears that thirty-five per cent. of all deaths coincided in time with the sudden defervesence, the only period more fatal than this being that of the highest fever. Cases attended with an average temperature of 103° F. presented the minimum of mortality, the states of apyrexia and of hyperpyrexia corresponding with the maximum of danger to life. Dr. Cohen has seen a number of cases in which cold applications seemed to do good. If any general rule could be laid down, it might be to use cold applications whenever they added to the comfort of the patient; when they added to his discomfort, it may be inferred that they are harmful. A similar rule would apply to the use of hot applications.

DR. ERNEST LAPLACE maintained that the fever of pneumonia is a direct product of toxins circulating in the blood, resulting from the activity of the pneumococcus, and acting upon the thermogenic centers. It has been found that most violent diseases, surgical or medical, attended with high fever, have a tendency to recovery, while those attended with less fever display less of this tendency. Violent disturbances of the body, attended with high temperature, seem to lead to alterations of the soil that render this unfavorable to the life of the invading germs.

DR. J. C. WILSON emphasized the statement that the height of the temperature is not an index of the severity of the disease. There is no reason to believe that the application of cold to the chest has any direct influence upon the blood vessels of the interior of the lungs. It does, however, relieve pain, lower respiration, and reduce temperature. There is also no ground for believing that it limits the exudate or hastens crisis.

DR. J. P. C. GRIFFITH said that in watching the treatment of pneumonia with cold at Vienna years ago he found that it relieved pain, but did not influence the progress of the disease.

DR. M. V. BALL said that children between the ages of four and twelve with croupous pneumonia bear the treatment with cold very well, being relieved of pain and sleeping comfortably.

DR. MAYS in conclusion added that at first he had treated only cases of acute pneumonia with cold, but that the reports in cases of all kinds were so favorable that he did not continue to make the discrimination. While fever is not an index of the severity of the pneumonic process it is also no index of the degree of thermotaxic disturbance. Dr. Mays maintained that in many cases the local application of cold not only limits the pneumonic process, but that when applied early enough it cuts short the disease. While a temperature of 104° F. may not be dangerous to life in most cases, most physicians prefer to see a lower temperature; so that while fever may be a good thing for the disease it is a dangerous experiment for the patient. While the treatment with cold is not applicable to all cases of pneumonia it is available in the majority. It is not asserted that general bathing is useless in the treatment of pneumonia, but the best results are to be secured from the local application of cold.

ANNOUNCEMENTS.

THE STATUS OF PULMONARY TUBERCULOSIS IN NEW YORK CITY, AND ITS CONTROL BY THE BOARD OF HEALTH.

NEW YORK, January 11, 1897.

HON. CHARLES G. WILSON, PRESIDENT OF THE BOARD OF HEALTH.

SIR: Nearly eight years ago the Health Department of the City of New York took its first steps in the education of the people regarding the communicable and preventable character of pulmonary tuberculosis. At that time this view of the nature of tuberculosis was held by only a very small proportion of the medical profession; now it is not only the universal conviction of the medical profession, but also a wide-spread belief among the laity, that pulmonary tuberculosis results solely from the transmission of infectious material from the sick to the well, and is wholly preventable.

It is a little more than three years since the Board determined that the time had arrived when more energetic measures for the prevention of this disease could be properly taken, and adopted resolutions requiring the notification of all cases occurring in public institutions in this city; the inspection of premises in tenement house districts, the instruction of the occupants, when reported as suffering from tuberculosis, and the renovation, when required, of all rooms or apartments occupied by consumptives, which had been vacated by death or removal. The Board also at this time offered to assist physicians, free of charge, in the diagnosis of cases of suspected tuberculosis by the microscopical examination of the sputum.

The action of the Health Department in relation to this disease has always been as nearly abreast of the knowledge furnished by the most advanced scientific investigations as was practicable, and the methods adopted in the past have been followed by the most encouraging results.

The Department has cause for extreme gratification in the marked increase in intelligence and care, especially among the poor, which is observed in the presence of this disease, as the direct outcome of its conservative and educational policy, and in the proportionate curtailment of the danger and the suffering incident to it. During the past twelve years there has been a reduction of more than thirty per cent. in the general mortality from all tubercular diseases in New York City.

But the time has now arrived, we believe, when more comprehensive and radical measures should be adopted to rapidly and materially diminish the prevalence of pulmonary tuberculosis in this city.

Some idea of the enormous sanitary importance of the subject is obtained by reference to the records of the Department showing the reported cases and deaths during the past year. Nearly 9000 cases of tuberculosis were reported to this Department, and nearly 6000 deaths resulted from this disease. It is conservatively estimated that at least 20,000 cases of well-developed and recognized pulmonary tuberculosis now exist in this city, and an additional large number of obscure and incipient forms of the disease. A very large proportion of the former cases constitute more or less dangerous centers for infection, the degree of danger depending, in each instance, upon the intelligence and care which is exercised in the destruction of the expectoration. It may be safely assumed that from the failure to safely dispose of the sputum of consumptives, from thirty to fifty inhabitants of this city daily become infected by tuberculosis, and of these about one half later die from the disease.

All this suffering and death, in view of modern scientific knowledge, we know to be largely preventable by the efficient enforcement of simple, well understood, and easily applied methods of cleanliness, disinfection and isolation.

The knowledge now at command regarding the methods of extension of pulmonary tuberculosis entirely justifies the belief that its ravages can as certainly be limited by proper sanitary control and appropriate treatment as can other infectious diseases, more acute, more dramatic, and more readily communicated, but at the same time far less prevalent, less fatal, and incomparably less important to the welfare of the community. We fully believe that with proper regulations tuberculosis may be restricted within the narrowest bounds, and eventually, perhaps, almost exterminated. This is not the idle dream of sanitary enthusiasts or theorists, but is a conviction founded upon the most thorough and conclusive experimental investigations, which have been amply confirmed by practical experience.

In order to make possible such restriction in the prevalence of this disease, it is necessary that the Health Department shall assume a more complete and comprehensive control. This requires, first, the adoption of such measures as shall make possible the general sanitary supervision of pulmonary tuberculosis under well-defined conditions and regulations, differing in many respects from those applied to other more readily communicable diseases; second, the possession of such facilities for the care of the poor suffering from it, as shall make possible the removal, when necessary, of those who are dangerous sources of infection.

From the beginning of this work the officials of this Department have encountered, in the utter lack of proper facilities for the care of consumptives, an obstacle to practical success so great, and so disheartening, that we feel impelled to urge our conviction that the grave responsibilities which rest upon the Health Department in this matter cannot longer be adequately sustained without the immediate establishment, under its direct control, of a hospital for the care and treatment of this disease. No week passes in which the officials of this Department do not encounter many instances in which the members of many households, numerous inmates of crowded tenement houses, employés in dusty and unventilated workshops, and many others, are exposed to imminent peril from victims of this disease, to whom either the doors of our over-crowded public institutions are closed, or who reject all proffered assistance and instruction, and, from ignorance, indifference or inability through weakness due to the disease scatter infectious material broadcast, and thus diminish their own chances for recovery, and imperil the health and safety of others. In such cases the sanitary suggestions of the Health Department Inspectors are now futile, and effective action impossible. We are convinced that no other factor is so potent to-day in perpetuating that ominous death list from pulmonary tuberculosis, as the lack of proper facilities for the care of the poor of this city stricken with this malady.

The best medical opinion forbids that persons suffering from pulmonary tuberculosis be treated in association with other classes of cases in the general medical wards of general hospitals. This opinion is based on the daily observation that consumptives, when occupying hospital wards in common with other classes of cases, not only constitute a serious source of danger to other patients, but that they are themselves placed under peculiarly unfavorable conditions. This is an opinion which the former action of this Board has done much to establish and extend. It has very properly resulted in the exclusion, to a large extent, of persons suffering from this disease from many of the general hospitals to which they were formerly admitted.

The special hospitals for the treatment of pulmonary tuberculosis now existing in this city, are not free public hospitals, and are quite unable to meet the demands upon them by the poor. Much larger numbers than formerly of this unfortunate class of sufferers are forced to seek admission to the already over-crowded institutions of the Department of Public Charities, as other doors are closed to them; so that further provision for them must, of necessity, be made by the city. These cases appeal for care at all stages in the course of the disease, but, as a rule, seek for admission to the hospitals only when suffering with well developed, or advanced forms of consumption.

The Department of Public Charities is not able to provide separate accommodations, excepting to the most limited extent, even for these advanced cases, and, as a result, actual isolation does not exist in any of the municipal institutions. In every one of the institutions of the Department of Charities and the Department of Corrections consumptives are found occupying beds in the general wards of the various hospitals; associating with healthy prisoners in the cells, and in the greatly over-crowded work-rooms of the work-house and the penal institutions. Many of these cases, as we know from careful investigations, are sources of actual danger to their associates. No precautions whatsoever are taken with regard to the expectoration in many instances, and everywhere the precautions taken are utterly insufficient.

A communication has been referred recently to this Board by the Honorable Commissioner of Corrections regarding numerous cases of pulmonary tuberculosis which exist in the Workhouse, with the inquiry whether this Department could not, in some way, care for them. An investigation has shown that there are many cases of pulmonary tuberculosis among the inmates of the Workhouse; that these are, in part, in the hospital wards, and, in part, are among the well inmates in the sewing and work-rooms, which are badly ventilated, dusty, and excessively over-crowded. It was found that in these rooms there were no sanitary provisions whatsoever in regard to the expectoration, and the most favorable conditions existed for the transmission of the disease.

Over 2200 cases have been reported to this Board as admitted during the past year to the various institutions under the charge of the Department of Charities, and 900 cases in addition have been treated in the various dispensaries under the charge of the Department of Charities.

As the Health Department has already declared its conviction that pulmonary tuberculosis is a communicable disease, and has taken steps looking toward its prevention, and as the information at hand shows that it is far more fatal than any other communicable disease with which the Board has to deal, and destroys each year more lives than all the other communicable diseases together, it would seem self-evident that some efficient and far-reaching measures should be at once adopted to protect the inhabitants of this city from its further ravages.

The importance of provision for the separate care of persons suffering from other forms of communicable disease has long been universally admitted, and the maintenance of separate hospitals for these diseases is justly recognized as one of the most effective of the sanitary measures for securing public safety. There are most urgent reasons why similar measures should be adopted in dealing with pulmonary tuberculosis.

A large experience in this matter has shown that in institutions devoted solely to the care of consumptives, the general welfare of the patients is more easily fostered, the risks of fresh infections more certainly diminished, and the chances for recovery more surely enhanced than in general hospitals in which all classes of cases are received.

We believe that such an institution in charge of the Health Department would secure all these advantages, without encroaching in any way upon the province of the institutions now caring for such patients, and would contribute, as no other measure can, to the success of the endeavor of the Department, now pursued in the face of hopeless obstacles, to curtail the ravages of pulmonary tuberculosis in New York.

We would, therefore, respectfully recommend:

1. That such action be taken by the Health Board as seems necessary and proper to at once secure the provision of hospital accommodations, under its charge, for the care of the poor suffering from pulmonary tuberculosis, who, as active sources of danger to the community, may properly come under its supervision.

2. That an amendment be made to the sanitary code declaring that tuberculosis be officially considered a communicable disease, and formulating regulations under which its sanitary surveillance shall be exercised.

3. That all institutions in this city which admit and treat cases of pulmonary tuberculosis be subjected to regular and systematic inspection by officials of this Board, and that specific regulations be established for the conduct of such institutions, in accord with the proposed amendment to the sanitary code.

4. That the scope of the measures designed for the education of the people in regard to the nature of pulmonary tuberculosis, and the methods to be taken for its prevention, be enlarged, and a closer sanitary supervision be maintained over individuals suffering from this disease in the densely populated tenement districts, and in the crowded work-shops and public buildings of this city.

(Signed) Hermann M. Biggs, M.D.,
Pathologist and Director of the Bacteriological Laboratories.

Consulting Pathologist.

Approved by the Board of Health of the Health Department, at a meeting held January 12, 1897.

Emmons Clark, Secretary. Charles G. Wilson, President.

ATTENUATED TEST CULTURES AS A SAFEGUARD AGAINST PSEUDO-REACTIONS IN SERUM DIAGNOSIS OF TYPHOID BY THE DRIED BLOOD METHOD.

To the President of the Board of Health of the Province of Quebec.

Sir: In my work on serum diagnosis, done jointly with Dr. D. D. MacTaggart, we recently met with a series of peculiar partial reactions in which the dried blood solution from many perfectly healthy persons gave a very decided agglutination. The blood serum from the same persons was found much less liable to give these pseudo-reactions. This made it less easy to exclude other febrile diseases, and as with this test, accuracy in the negative diagnosis is of great practical importance, others who may meet with similar pseudo-reactions will be interested in learning how they may be avoided.

These pseudo-reactions were not encountered in our earlier cases when attenuated cultures were used. They began to appear when we employed the short time virulent cultures, and disappeared again on resuming the use of attenuated ones. Active, virulent cultures intensified by daily transplantation and growth at the body temperature, were therefore not suitable for the dried blood test. Where only active cultures are employed, we do not think that the dried blood method can be considered to have had a fair trial.

The explanation of this difference appears to be that the serum contains relatively less of the substances causing agglutination than solution of the entire blood. Hence solutions of the entire blood react more intensely to the test than solutions of the blood serum alone. This was the reverse of what we had anticipated.

It is found that old laboratory stock cultures kept at room temperature and transplanted at intervals of about one month give us the best result. Bouillon test cultures grown from this stock for twelve to twenty-four hours at body temperature, are found to react decisively with solutions of typhoid blood or typhoid serum, the reaction being as a rule well marked within fifteen minutes. With non-typhoid blood or serum solutions, the same test cultures give no reaction even after twenty-four or forty-eight hours' contact. Intra-peritoneal injection of 1 c.cm. of such living bouillon culture produces in guinea-pigs a marked blood reaction and immunity without much disturbance of health. We find that the best results in cases of dried blood are obtained with cultures where the motion, as seen under the microscope, is of a rapid gliding character, but free from darting movements. If the movement is sluggish, owing to too great attenuation of the culture, a few daily transplantations at body temperature will make it more active. Exact estimation of the degree of dilution has not been found necessary for ordinary diagnostic work when attenuated cultures are used. A very faint tint in the drop examined usually indicates sufficient strength. The solution should not be thick or viscid.

All the results which I have reported (*New York Medical Journal*, October 31, 1896, and *British Medical Journal*, December 5, 1896) were obtained with attenuated cultures. A report giving some additional technical details has been prepared and will be sent to any who desire further information.

I remain, yours respectfully,

Wyatt Johnston,
Bacteriologist to the Board of Health, Province of Quebec.

THE SURGICAL ENGINE AND ITS USE IN BONE SURGERY.[1]

BY MATTHEW H. CRYER, M.D., D.D.S.,
OF PHILADELPHIA.

THE requirements of a satisfactory surgical engine are, first, that it be so geared that the velocity of the cutting tool is from four to six thousand revolutions per minute, which speed is to be maintained under varying pressures. The hand-piece (the chuck which holds the instrument) should be light, capable of easy adjustment, and so arranged that the instrument fixed in it may be carried with readiness into the recesses of deep cavities. There should be no undue vibration of the instrument while held to its work as this will lessen tactile recognition of the nature of the tissue being cut. The motive power should be so arranged that it is under perfect control and produces steadiness and uniformity of speed. The hand-piece and its several parts, with the instruments used, must be of such character that perfect sterilization can be readily accomplished.

Surgical engines of several designs have been in use for many years, but, strangely enough, few general surgeons appear to have availed themselves of the advantages to be derived through their use, preferring the use of hand-tools—saws, gouges, chisels, mallets, hand-drills, and heavy cutting forceps—for their operations upon the bones. There is scarcely an operation upon osseous tissues that could not be more quickly and accurately performed by means of the engine than with any of the hand-instruments used. Many of these latter are crushing instead of cutting instruments. This singular preference has always appeared to me to be akin to a carpenter choosing hand-tools when a molding machine is available.

Objections to some of the older forms of engines were not without good foundation. As they were chiefly notable for their faults of design and of construction, the deficiencies in mechanical performance might be accepted as a necessary evil, but the impossibility of complete sterilization was an objection not so easily disposed of. These serious drawbacks have one by one been corrected, until in its present form the engine combines all of the features described as requisites of a correct machine. It is simple in design and accurately built, so that there is little liability of the mechanism getting out of order.

The performance of a series of operations upon the cadaver will readily give any surgeon a mastery of the instruments and mechanism. As with all other machines, some practice is required to give perfect control of it. The present form of hand-piece may readily be rendered aseptic.

So far as my personal knowledge goes, the first use of the engine in surgery was made by Dr. Harrison Allen of Philadelphia, in 1876, when he removed an osteophyte from the mouth of a patient by means of it. When the late Professor Garretson founded the Hospital of Oral Surgery in Philadelphia he obtained an enlarged and modified cord engine, turned by means of a crank. It was known as the Bonwill surgical engine. With all its defects of design and construction, this apparatus was of marked service, and was the progenitor of the recent forms of the surgical engine, notably of the one exhibited at the World's Columbian Dental Congress, in 1893. A description of this engine will be found in the proceedings of the Congress. Extended and accurate observation showed this engine to be too heavy and complicated to fill the needs growing out of an increased refinement and delicacy in modes of operating. The engine was not readily portable—that is, it could not be readily taken apart and packed in a small case for shipment; the hand-piece was not of a form which would permit of easy sterilization, and would not carry an instrument of thick enough shank to prevent vibration in certain classes of operations.

The present engine is new in nearly all of its features; it is simpler in design, lighter in construction, and its parts are readily detachable to permit of packing in a small case—a box not larger than those made for croquet sets. The hand-piece is designed with a twofold object—first, with a reference to the mechanical, second, to the pathological elements involved. It is sufficiently rigid to carry its tools steadily while operating upon dense bone, and may readily be rendered perfectly aseptic. The latter point is repeatedly emphasized because of the serious objection to previous hand-pieces, involving the existence of spaces which commonly retained septic matter. That portion of the engine which transmits the power from the large wheel to the pulleys of the hand-piece requires no description other than that of the illustration. The engine is driven by an electric motor of one-sixth horse-power.

---

[1] The substance of this paper was read before the Odontological Society of New York, November 17, 1896.

For office practice, and when driving by electricity, the upright shaft from above the crank and the "arm" may be attached to a bracket. This plan is excellent when the engine is used in bone surgery of the nasal fossa or other light surgery about the face or ears; but for hospital and heavy work it is better to use the stand, as it can be moved about to suit the convenience of the operator.

The hand-piece has undergone complete change, in order that the several appliances used can be made absolutely aseptic and kept so throughout the operations. All that portion of the instrument which includes the hand-piece and its wrist-joint attachment, except the cord, can be throughly boiled under pressure. The hand-piece proper is detached from the pulley after the parts have been sterilized; the pulley is adjusted and the cord placed in position; the hand-piece or pieces, after sterilization, are kept in a tray containing a carbolic acid or lysol solution until used. When the surgeon is ready to use the instrument, his assistant holds the pulley attachment in such a manner that the hand-piece can be adjusted without the hand coming near the cord or that portion upon which it works. For ordinary surgery, one hand-piece is quite sufficient, as any number of instruments can be easily adjusted by opening the key-latch and inserting the sterilized instruments, which are also placed in a tray containing the antiseptic solution. For opening the brain-case it is preferable to have two hand-pieces—one with the small trephine and one with the spiral osteotome and guard adjusted. It saves time, an element of some importance in these operations.

Among the various uses for which the surgical engine is well adapted is the removal of carious bone from almost any of the bones of the body. This may be done without danger of injuring the surrounding tissue, for, when properly manipulated, operations may be performed without injury to the periosteum of the bone operated upon.

The engine has also been most successfully used in mastoid and other operations on the temporal bone and upon the nasal fossæ; also for removing caries and necrosis of the maxillary bones. The removal of even the greater portion of these bones may be accomplished without external incisions, which gives greater advantage over the older methods of operating with the cutting forceps and saws, as the parts are left smooth and rounded, not jagged and roughened.

The engine has also been used extensively in opening into the inferior dental canal or cutting through the ramus of the inferior maxillary bone to reach the inferior dental nerve; also in opening through the superior maxillary bone for resection of the second division of the fifth nerve. Another office which the engine has been called upon to fill is the opening of the brain-case with the absolute certainty of not injuring the brain or its covering membranes.

In October, 1893, the surgical engine was first used in the operation for removal of the Gasserian ganglion by Professor W. W. Keen, for report of which see Transactions of the Philadelphia Medical Society for 1894. In this case a revolving saw, with guard, was used to cut the outer table and diploë, the inner plate being broken through by mallet and chisel. During the discussion of the report of this operation before the Society, Dr. John B. Roberts made the following remarks: "With regard to this elaborate instrument, it seems to work very satisfactorily, yet for my own work I should rather use a sharp chisel with my own hand and my own mallet than any mechanical device. These are apt to get out of order, and must be at some place where they can be kept in order. What we want to do is to train our own hands to do the work, and not be dependent upon any mechanical device." This statement indicates to me a false position with regard to this class of instruments which it seems to me ought not to go uncorrected.

With all due respect and admiration for the ability of Professor Roberts, I am a little fearful that surgery would take a backward step if all its mechanical devices were done away with. I heartily agree with him when he says that "what we want is to train our hands to do the work," and I would strongly advocate the highest possible attainment of manual skill as a necessary prerequisite in the performance of all surgical operations; but when he adds that we should "not be dependent upon any mechanical device," I am inclined to take issue with him on the ground that his statement is contradictory, from the very fact that he himself advocates the use of a mechanical device, albeit a very crude one, in the shape of a mallet and chisel. After having used a dental or surgical engine for eighteen years, in all kinds of bone operations, I consider this engine as far in advance of chisel and mallet in bone surgery as the Pullman car is ahead of the canal boat in traveling.

It was decided during the operation referred to for removal of the Gasserian ganglion, and after a series of carefully-conducted experiments upon the cadaver, that the danger of wounding the membranes of the brain, and even the brain itself, had not been altogether obviated. This insecurity was partly due to the fact that brain-cases vary in thickness, and even the individual skull is thicker in some parts than in others, thus making it impossible to use a fixed guard when working from the outside of the skull. It was desired to cut entirely through the bone down to the dura mater with the engine, thus avoiding the use of the mallet and chisel, and after many trials with various burs, saws, etc., the following arrangement was devised, which has completely fulfilled the requirements, as many brain-cases have since been successfully opened with it: The cutting portion of the instrument, called a spiral osteotome, is one-half an inch in length, and one-eighth of an inch in diameter, and tapers slightly from base to point. It is divided by three spiral grooves, each having a turn of 120° through the half-inch from the base to the point of the cutting end, the arrangement of its three blades giving it the appearance of a twist drill. The point of the bur, when in use, is guarded by a button-like attachment, connected with the nose of the hand-piece by means of a shank and collar. The free end of the bur is doweled into a seat in the guard, in which it revolves, which steadies the whole arrangement when in use, gives an added rigidity to the bur-shank, and holds the bur and guard in permanent relationship to each other.

The principle involved in the instrument described is simply that of a saw arranged to cut in a line with the axis of the shaft of the bur, and not at right angles to it, as in the circular saw. Such an arrangement allows of cutting in any direction and upon curved lines. This feature is especially valuable in resections of the brain-case, inasmuch as fenestra of any desired shape or size may be speedily made.

The mode of opening the brain-case by means of the spiral osteotome is as follows: After division of the soft tissues by the scalpel, a small opening is first made with a trephine mounted in the engine hand-piece; this trephine has a diameter of five-sixteenths of an inch, and is passed completely through both tables of the skull and the button of bone removed. There is no danger of injuring the dura with the trephine if it be carefully used by one who has had a little training with the instrument upon the cadaver. The opening thus made affords a means of entrance for the osteotome, with its protecting guard, which is next inserted in the opening and the section made along the lines previously determined by running the engine at high speed and forcing the bit laterally in the direction desired. The button-like guard at the point of the osteotome absolutely prevents injury to the dura, which is pressed or dissected away by it from its attachment in the lines of the cut as the instrument progresses.

The instrument as a whole has been designed not only with reference to the mechanical requirements imposed by the dense tissues which are to be operated upon, but with a full recognition of the demands which the later developments of bacterio-pathologic research have made a requirement in all surgical procedures, *viz.*, rigid asepsis of the instruments used.

DISCUSSION.

Dr. R. F. Weir: I am only too pleased to express my gratification at seeing this instrument to-night. It far exceeds my idea of its capacities, and I was especially impressed with the satisfactory way in which the deviser of the machine performed the operation. The only weak point I see is the use of the preliminary trephine opening. It is liable, even in experienced hands, to do damage to the dura and the brain, for I have used the trephine with the electric motor a number of times, and I have found that sometimes I could avoid injuring the dura and sometimes

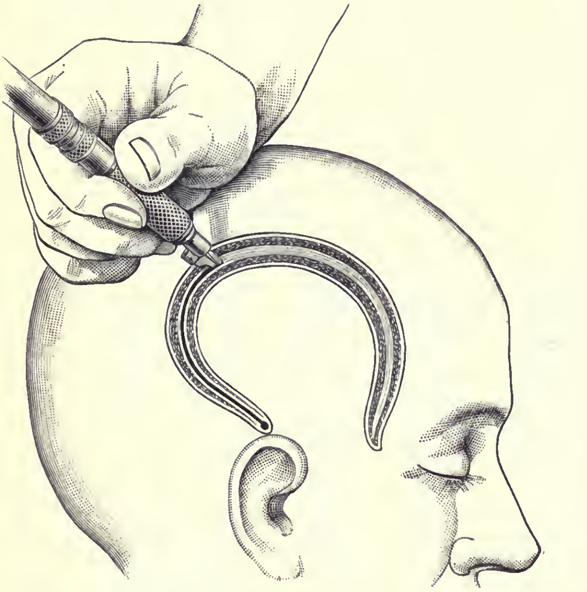
not. Entrance, however, being once made into the skull—I should prefer for this the Flower hand-trephine—I see nothing to prevent the use of the instrument, and I hope soon to have the opportunity of using it in the New York Hospital. Something of this kind is of great value. I feel that I cannot add anything more, except to renew my thanks to the exhibitor and to the society for the opportunity of being present at this demonstration of the ability of the improved machine.

Dr. G. E. Brewer: My experience in this department of surgery has been rather limited, but it strikes me that this instrument is by far the most satisfactory one I have seen for opening the cranial cavity. An important question, however, arises in my mind, and that is, would it be possible with this instrument to make an oblique cut through the bone, so that the edge of the bone-flap would be beveled? as it is important, in replacing the bone, to avoid a depression of the flap below the surrounding portions of the skull. In the operation shown to-night this was not done, but I see no reason why it could not be accomplished. It is certainly of advantage to save time in these operations. In the cases upon which I have operated, it required from ten to fifteen minutes to remove an omega-shaped flap of bone three inches in diameter. With this instrument the same work can be done in two or three minutes. I think with Dr. Weir that if more safety could be insured against wounding the dura by the preliminary trephine-opening, the value of the instrument and method would be enhanced.

FIG. 2.



Method of removing section of skull with cutting tool, the guard being in close contact with the internal surface, thus preventing injury to meninges.

Dr. Cryer: My experiments on the cadaver were not at first encouraging; the instrument seemed inclined to slip, and would not cut as I wished, but after a little practice this difficulty was overcome. The hand-piece should be held like a pen, with the third and fourth fingers resting upon and near the parts to be cut, which should also be firmly held. In using the spiral osteotome, the third and fourth fingers do not rest upon the head. Mechanical guards can be used to prevent the danger of the trephine plunging into the brain; but by holding the instrument properly, one who is accustomed to operations upon the cranium can, by a little practice, operate with safety without the guard, and even tell, by feeling alone, what kind of bone tissue he is cutting or when nearly through the walls of the skull.

When it is desired to return the flap of bone, and also in working with skulls of ordinary thickness, I would not recommend the use of as thick an osteotome as I have used on this negro's very thick skull; by using a thinner one, the kerf would not be so wide. It is well in some cases to use an irrigating bottle, which keeps the parts clear while being cut.

The instrument has been successfully used in making artificial sutures for children whose natural sutures have fully ossified and prevented the expansion of the brain and the enlargement of its encasement. In this operation, make the linear incision in the integument for the longitudinal suture a little to one side of the median line, to avoid the longitudinal sinus. Then it is well to trephine at the anterior and posterior ends of the line to be cut, when the instrument can be inserted at the end most convenient and the bone cut to the other opening. If an artificial fronto-parietal or occipito-parietal suture is desired, then the instrument should be entered at the anterior or posterior trephined opening and carried in the direction desired. The instrument has been passed between the longitudinal sinus and the bone without injury to the former. The guard will push an artery or vein out of its groove in the bone; but should the artery be inclosed in a canal, as is sometimes the case with the meningeal arteries, the osteotome will cut the vessel.

Dr. Blackman: While my experience in brain surgery has been exceedingly limited, I will say that I have seen some operations performed by Horsley of London, who, as an authority, is perhaps unquestioned. I have never seen anything so complete for operations on the brain-case as this instrument and its appliances. Mr. Horsley has discarded the mallet and chisel entirely, and depends upon the hand-trephine and bone-forceps of his own design. One unquestionably needs to learn how to handle the instrument. You cannot use the old trephine successfully without knowing how to handle it. I think this instrument would be particularly useful in forming new sutures, as Dr. Cryer has just said, and especially in cases of operations for allowing expansion of the brain-case in cases of idiocy, where a new suture can be formed without the removal of bone, by making this strip.

Dr. John B. Walker: I will simply say that I am very much pleased with the machine. I appreciate very much the saving of time by its use. I do not think there is anything further, unless it be that the drill could be made smaller. I suppose that could not be done and the instrument still have the same strength.

Dr. B. F. Curtis: I have been very much interested in this instrument. I think possibly one reason why the small trephine is not so apt to cause injury to the dura is on account of its size, as the large trephine is more likely to cut too deeply at one edge. The great advantage of this method of opening the skull is the avoidance of shock from the repeated blows of the mallet upon the chisel, which is a serious item, and also the great saving in blood, because the bone would be lifted out so rapidly that the vessels of the diploë, which give us so much trouble, and from which the patient may lose a couple of ounces of blood in the operation with the hand-trephine, would not have time to discharge so much blood before they could be reached and plugged. There would be a saving of blood as well as of time.

Dr. S. G. Perry: It seems to me there is one point made by Dr. Cryer which should be emphasized. I suppose there is not a dentist present who does not know perfectly well that those burs, however sharp or coarse their blades may be, when revolving, do not cut on the soft as they do on the hard tissues. I have often quieted a patient who was afraid to have me use the bur by revolving a small bur between my fingers. Of course it would not hurt the soft tissue, but that would not be the case if the finger-nail or bone were touched. I believe one can readily feel when one is nearly through the bone, and that the sense of touch would be a better guide than anything else. Any one who has had any experience with the dental engine must know what I mean, and what Dr. Cryer means when he says he can tell when he is almost through the bone.

Dr. Jarvie: There was one point in the paper that attracted my attention, which related not so much to the use of the engine as to its history. I think Dr. Cryer said the first knowledge he had of the dental engine being used for surgical purposes was in 1875. A year prior to that Dr. Arthur Mathewson of Brooklyn, an oculist and aurist, came to me and said he had a patient who had an osseous tumor in the auditory meatus. He thought I might have some cutting instruments that were finer than anything he had. I suggested the use of the dental engine, and made a number of burs, taking the ordinary fissure-bur and grinding it to the desired point. The operation was performed by drilling with a fissure-bur through the center of the tumor, then using a larger bur of the same kind; into the opening thus made a round bur was passed and the tumor burred away, from the center outward. That was certainly twenty-one or twenty-two years ago. The operation was successfully performed, the patient's life saved, and the hearing restored. I am speaking from memory, but, while I think I am correct, the date may not be exact.[1]

Another very valuable use to which this surgical engine could be put, and which has not been spoken of, is in removing necrosed bone, either of the long bones, or in any part of the body. With large burs in the engine, the necrosed bone could be burred away and the soft tissues disturbed but little. Certainly the simile that was made use of in the paper, —the difference of travel in a Pullman car and a canal boat, would be applicable to the removal of necrosed bone by the use of the engine in comparison to performing the same operation by the ordinary method.

Dr. Cryer: If in operating there are any sharp edges or points of bone left, as is sometimes the case in the removal of the superior maxilla, the finger can detect them, and the instrument can be carried in along with the index-finger, and the roughness be cut away. The instrument will not cut the finger unless it becomes caught between it and the bone. Crevices were left by the old-fashioned method of removing the superior maxillary bone, and germs of disease had ingress to the parts; but by the use of the engine these rough and deep depressions are avoided, leaving the parts even and smooth.

Recent Roentgen-ray Discoveries.—Professor Friedrich of Vienna is reported to have discovered certain black rays, called "critical rays," that issue from the Crookes tube, which, when passed through a living hand, present the skeleton as in the usual Röntgen photograph, but when passed through that of a cadaver present the fleshy tissues, while the bones remain invisible. The suggestion is made that this may prove a positive test of life or death, and thus obviate the possibility of premature burial.

---

[1] Examination of the records shows that this operation was performed in May, 1876. It was reported in full by Dr. Mathewson before the first Congress of the International Otological Society, held in New York, September, 1876, and was published in the Transactions of that Congress, pp. 86–96.

In a note received recently from Dr. Mathewson, he says: "The report of the operation received very flattering notices in the medical journals and reviews, both here and abroad; has been mentioned in every standard work on the ear published since; and this method of dealing with those bony growths in the ear has been generally followed."

TUMORS OF THE MALE BREAST.[1]

BY NATHAN JACOBSON, M.D.,
OF SYRACUSE, N. Y.;
PROFESSOR OF CLINICAL SURGERY, COLLEGE OF MEDICINE, SYRACUSE UNIVERSITY; SURGEON TO ST. JOSEPH'S HOSPITAL.

THE subject of tumors of the male breast is of interest because of its rare occurrence. Many physicians of large and varied experience have never encountered this pathologic condition. It is generally conceded by surgical writers that the forms of breast tumor met with in women are also to be found in the male breast. Although the literature is not voluminous, both innocent and malignant tumors of all types have been described in this connection. Perhaps the most elaborate statistical study of these tumors has been made by Shuchardt, and the results published in the *Archiv für klinische Chirurgie*, vol. xli. He collected 469 cases of tumors of the male breast. He found that fifteen per cent. of all tumors occurring in the body appear in the breast, while only one per cent. of breast tumors occur in the male. W. Roger Williams published in the *British Medical Journal*, vol. ii, 1892, the statistics of Middlesex, University College, St. Thomas', and St. Bartholomew's Hospitals of London, covering all primary neoplasms which had appeared during periods of from sixteen to twenty-one years prior to 1889, in these hospitals. There were in all 13,824 primary tumors, and of this number, 2,422 (or 17½ per cent.) were located in the breast. Twenty-five were in males and 2397 in females. It appears, therefore, from this large list of primary growths that the female breast is subject to tumor visitation one hundred times oftener than is the male. This group of cases, collected by Dr. Williams, includes 4597 cases of neoplasms in the male. Studying the relative frequency of site of occurrence of tumors in various parts of the body, we find that the male is afflicted most frequently with those affecting the skin—16.4 per cent. of his tumors occurring in this structure. Next in frequency is the tongue and mouth. Here 15.9 per cent. occur, while neoplasms of the mamma occur in but one-half of one per cent. of the cases.

The disposition to malignant tumors in the human body is nearly twice as great as it is to innocent ones. In the breast, an enormous disproportion is manifested, for here 81.7 per cent. of all tumors are malignant and only 18.3 per cent. benign. It is interesting in this connection to study the influence of sex upon the particular kind of tumor found in the breast. In the table of Williams, 2422 consecutive primary breast neoplasms were included. Of this number, in the male there were 16 cancers as against 1863 in the female. Three cases of sarcoma were found in the male and 92 in the female. Of myxomata, peculiarly enough, each sex exhibited 2 cases. Fibro-adenoma occurred once in the male, and 372 times as frequently in the female. Cystoma put in an appearance in the male once as against 63 times in the female. It is very evident, therefore, that primary neoplasms in the male breast are not of common occurrence. Writing in 1880, Billroth said, in the *Deutsche Chirurgie*, that fibroma, cystosarcoma, and adenoma, as far as he could learn, had never occurred in the male breast. On the other hand, he had encountered personally 7 cases of carcinoma in the breast of the male, as against 245 in the female. Their usual period of occurrence was after the fiftieth year. As far as he could determine, their course was exactly as it is in women. Sooner or later the axillary glands became involved, and death resulted after the same manner in both.

The breast gland in the male is smaller than in the female, and, being rudimentary, tumors involving it should be discovered at an earlier period. Being earlier discovered, radical measures can be applied sooner, and there should be a more hopeful outlook for them than is the case in the female.

Wagstaff, studying the question of the time of life at which cancer appears in the breast of the male, reports, in vol. xxvii, of the "Pathological Society's Transactions," 61 cases, in 40 of them the age being mentioned. Six were under the age of forty, 20 between forty and sixty years, 7 between sixty and seventy years, and 7 over seventy years. Other tumors have been found at a much earlier period in life. Thus Bryant, in his work on "Diseases of the Breast," reports the case of a male child ten months old, with a hard tumor, the size of a walnut, of four months' standing and rapid growth, located above and to the outer side of the left nipple, and freely movable upon the parts beneath, although the skin was adherent to it. It was excised at Guy's Hospital, July 22, 1874, and found to be a lipomatous adenofibroma. Dr. Thorburn described, in vol. i, 1890, of the *British Medical Journal*, a fibrous tumor, which he removed from a boy aged eleven. When first seen it was of the size of a hazelnut, but in the course of one year had grown to the size of a small orange. Authentic cases of carcinoma of the male breast, occurring at the age of thirty, have been reported by several observers, although a careful study of the recorded cases indicates that carcinoma appears a little later in life in the male than in the female; that is to say, rarely before the fiftieth year. It has been my fortune to encounter neoplasms in the male breast three times. A study of these cases may be of interest.

CASE I.—*Epithelioma:* M. T., aged seventy, a retired merchant, had always enjoyed good health. On September 18, 1888, he visited me, and said that for the preceding three months he had noticed a slight scab forming upon his left nipple. Beneath it there had been a sore. On the date mentioned, I found a tumor as large as a hen's egg, more nearly round in shape, movable, and non-adherent to any of the surrounding structures. It was surrounded by a rather extensive area of induration and its base was infiltrated. There were some enlarged glands in the axilla. On the 26th of September, 1888, a circular incision was made, the tumor removed, and with it a considerable amount of muscular tissue. The incision was carried well around the tumor, into apparently healthy structures. Drainage was employed, union was complete, and the wound firmly healed by the 3rd of October, one week after operation.

---

[1] Read before the Onondaga County Medical Society, Syracuse, N.Y., January 5, 1897.

The patient wore a woolen undershirt after his recovery, which, by rubbing against the skin, produced an erythema. This subsided under the protection furnished by dressing the chest with cotton and a carefully applied bandage. On the 13th of May, 1889, he consulted me again. A slight scaly eruption had appeared upon the inner extremity of the scar, and the skin had become quite irritable. On the 4th of July, when I next saw him, an ulcer had appeared, with evidences characteristic of its carcinomatous character. To this, zinc chlorid paste was applied, and two days later re-applied. After the expiration of a week, healthy granulations appeared, but from this time on small superficial ulcers would appear at intervals at various points, which were treated with pyrogallic acid. The disposition to repair was never marked; on the contrary, new superficial ulcers persistently appeared, until ultimately a large area of ulceration had again formed. Repeated efforts were made by means of minor surgical operations and the application of various escharotics to cure the diseased condition, but all to no avail. Not only did the disease manifest itself locally, but the patient grew quite helpless because of painful manifestations in various parts of the body. The glands in the axilla became badly infected, and the arm swollen and edematous. The patient ultimately succumbed to the disease, death occurring October 11, 1890, two years and three months after its first manifestations.

Case II.—*Sarcoma:* J. M. G., widower, aged seventy-seven years; had been a laborer, but for several years had not been engaged in any work. There was no family history of malignant disease, nor personal history of syphilis. He was unable to definitely state when the first symptoms of the tumor appeared. On the 17th day of January, 1891, I was requested by Dr. Mumford to see him, and found an irregular nodulated tumor of the right breast, adherent to the skin, but still movable below, with glandular involvement of the corresponding axilla. The tumor was about four inches in its long diameter and three in its transverse. The general health of the patient was unimpaired. His blood vessels were somewhat atheromatous. On the following day I removed the breast and its tumor, making a circular incision, going wide of the tissues apparently involved, and clearing out the axilla, as I then believed, absolutely. There was considerable bleeding, and a number of vessels required ligation. The resulting cavity was large and drainage was required. The patient made an uneventful recovery, and was discharged from my personal care on the 1st day of February, two weeks from the time of operation.

I did not see him again for a year, when he called upon me at my office, and I found a small movable glandular growth in the axilla. I advised a second operation, but the patient refused. The gland increased in size very slowly, and new points of infection appeared in the arm-pit. It was not until the 20th of February, 1894, more than three years after the primary operation, that I was called to see him again. The malignant infiltration had then developed into a mass, which not only occupied the axilla but reached over to the chest anteriorly, and posteriorly to the scapula. The axillary veins and lymphatics were compressed, and, in consequence, the right arm and hand were edematous and darkly discolored. The patient was suffering intense pain. He was quite anxious to have me perform another operation. This idea, of course, could not be entertained. From this date he failed steadily, and died soon after, four years subsequent to the primary operation.

My impression at the time of operating on this patient was that we had to deal with a scirrhus of the breast, as the growth presented the ordinary clinical manifestations. I was particularly led to make this diagnosis because of the presence of secondary glandular tumors in the axilla, but the pathologist of the hospital reported that it was a large spindle-celled sarcoma. The slow course of the case after operation, it seems to me, furthermore confirms this view.

Case III.—*Fibro-Adenoma:* E. M. R., aged fifty-two, married. Negative family history. On October 27, 1896, he called upon me and gave the following personal history: He had always enjoyed good health. In December, 1895, while convalescing from a broken leg and moving about on crutches, one of his crutches slipped, striking him in the left breast. Some time during the following spring, he noticed a small tumor in the breast, which was movable, of irregular outline, and not painful. Its growth had been quite rapid. When I saw it, at the above-mentioned date, its texture was firm, it was still freely movable, and not covered with large vessels. There was no glandular infection of the axilla. At the date of my examination it was about 4½ inches in its long diameter and 3 in its transverse. Its removal was advised. On the 4th of November I operated, making an oval incision. The tumor was readily dissected from the pectoral muscles, as it was not adherent to them at any point. The axilla was opened; there was but little fat, and no glands were abnormally enlarged. However, I emptied the axilla completely. Nowhere was there any suggestion of malignancy. The wound was readily closed.

I placed silkworm-gut drainage in the wound, using about one dozen strands.

He bore the operation poorly, and required strychnin and digitalis hypodermically, but after a few hours rallied. There was never any rise of temperature after the operation. His urine was retained for several days, and a catheter had to be used. He was able to leave the hospital ten days after operation.

Microscopic examination of the tumor showed it to be a fibro-adenoma.

While this list of cases is not large, it represents, I think, a larger number of tumors in the male breast in comparison with the number of tumors of all kinds that it has been my privilege to see, than should have been my due proportion, for, as will be recollected, out of the 13,824 cases, reports of which Williams was able to collect in the London hospitals, and to which I have referred, but twenty-five times in this large group was the male breast involved. It will be observed that both of the cases of malignant tumor which I here report, occurred after the seventieth year of life. In neither was the course rapid, nor did the advanced age of the individual seem to render the disease more malignant. To what extent the very painful manifestations in parts of the body remote from the diseased area were awakened by the cancerous infection in Case 1, I cannot say. There were no evidences of malignant disease of the spinal cord, nor of secondary growths at any of the painful sites.

Koenig calls attention to the frequent occurrence of epithelioma in the nipple of old men, although Billroth, in the article from which I have already quoted, states that he had never seen such a case, nor had he found in literature a reliable record of any. No doubt many of these cases begin with that eczematous affection described as "Paget's nipple." I have, however, found the record of a number of cases, in which true epithelioma has destroyed the nipple and breast of the male, and has been followed by cancerous invasion of the axilla, and in consequence of which the individuals have died of cancerous cachexia. Sarcoma of the breast seems to occur about one-fifth as frequently as cancer. While the latter attacks the male breast once where it does the female one hundred times, sarcoma in the male seems to occur about one-third as frequently as in the female.

I cannot but feel that, had I been allowed in my second case to remove the secondary growth one year after the primary operation, in view of the slow progress made by the disease after this period, we might still have had a successful termination to our operative work, despite the advanced age of the patient. Fibro-adenoma appears to be the most rare condition encountered, as in the large list of cases which I have quoted it occurred but once in the male breast as against nearly four hundred times in the female. While tumors of the male breast, as is apparent, present no unusual features except as to their rarity, I have felt it wise to add these cases to the rather small list in our surgical literature.

THE PREVENTION OF THE SPREAD OF CONTAGIOUS DISEASES.[1]

By HENRY DWIGHT CHAPIN, M.D.,
OF NEW YORK;
PROFESSOR OF DISEASES OF CHILDREN AT THE NEW YORK POST-GRADUATE MEDICAL SCHOOL.

The wide existence of contagious diseases, their fatality, and their crippling after-effects makes the subject of prevention of the greatest importance. The question can be attacked with more chances of success now that bacteriology has thrown so much light upon the causation of disease.

A word about infection and contagion may not be inappropriate. According to Prudden, an infectious disease is one which is caused by the invasion and reproduction within the body of pathogenic microorganisms—not necessarily an invasion by bacteria, because, in one case at least, malaria, the invading pathogenic microörganism is not a bacterium, but belongs to an entirely different class. According to the same author, the contagium in any infectious process is the particular pathogenic microörganism itself, the advent of which in the body ushers in those reactions of the body cells which we call disease. An infectious disease is contagious when its contagium, that is, the microörganism which causes it, *under the ordinary conditions of life* can be freed from the body of the diseased person, and, by whatever means, conveyed to the body of another in a condition capable of lighting up the disease anew. The particular contagia of contagious diseases may be given out from the mucous membranes, from the skin, or from the various discharges of the body. The prevention of contagious diseases can only be secured by attacking the virus at its source before it has had time to disseminate itself by means of the atmosphere, or water, or in the earth. Infectious diseases may thus prove slightly contagious, or widely contagious, according to the active means taken to destroy the virus as nearly as possible at its source. Hence, the degrees of contagiousness or communicability can be influenced by the physician's art, and it is his duty to exert all the means known to science in such a direction.

A knowledge of the natural history of any given contagious disease, and the sources and life-conditions of its contagium, will best indicate how the virus may be rendered innocuous and unable to spread. This may prove comparatively easy in some cases, and almost impossible in others. Thus it is well known that the virus of scarlatina and diphtheria cling to the patient, and direct contagion from these diseases is therefore limited to a very small area, probably one or two feet; but they are essentially portable diseases, and antiseptic inunctions of the skin in the former, and frequent antiseptic gargles in both diseases should be employed to prevent a dissemination of the virus. Measles and pertussis, on the other hand, have volatile poisons, and therefore are not so easily confined to a small area. The subject of proper and complete disinfection is one beset with difficulties in the present state of science, as modern bacteriology has taught us that disinfectants do not disinfect. All germs being in intimate contact with protoplasm, they are with difficulty reached by the disinfecting agent. The cell body of a bacillus is surrounded by a substance resembling cellulose, and this, in turn, by mucoid matter, hence they collect in masses that are difficult to penetrate. The disinfectant is apt to come only in contact with the outer substance, and thus bichlorid of mercury, for instance, becomes innocuous by forming an albuminate of mercury. In order to kill, the disinfectant must come directly in contact with the microprotein, or albuminous constituent of the bacillus. Citrate of silver (1–4000) has recently been stated to be a true disinfectant, as have formalin and methyl violet (pyoktanin). According to McFarland, the value of antiseptics, like that of disinfectants, is always relative, the destructive as well as the inhibitory power of the solution varying with the microörganism upon which it acts. The following table from Baer will illustrate this:

---

[1] Read at a stated meeting of the New York Academy of Medicine, January 8, 1897.

METHYL VIOLET (PYOKTANIN).

	Arrests.	Kills.
Anthrax baccillus........	1–70,000	1–5000
Diphtheria...............	1–10,000	1–2000
Glanders................	1–2500	1–150
Typhoid.................	1–2500	1–150
Cholera spirillum........	1–30,000	1–1000

I have used a spray of methyl violet in weak solution with good results in a case in which bacilli persisted in the throat after diphtheria, and when it was extremely important for the patient to see many people. Although bacilli have not been demonstrated in many contagious diseases, their virus will probably respond to disinfectants in the same way. It seems best, in the present state of our knowledge, to constantly apply some antiseptic or so-called disinfecting agent as nearly as possible to the source of the poison, and thus prevent a multiplication of the virus, ending with boiling or burning as many of the objects as possible that have been in contact with the patient during the progress of the disease.

Mr. Thomas F. Raven, in the *British Medical Journal* of July 24, 1886, states some interesting facts, to which my experience has usually lent corroboration. He says: "A short incubation period precedes, as a rule, a sudden, sharp illness, which will run either a short or a long course, with a long-continued infective power, being often prolonged by relapses, and having sequelæ of a definite and important character. It may thus be regarded as an axiom that the duration of incubation and the duration of infection bear an inverse ratio to each other. Again, when the incubation of a disease is long, the infection, even the most powerful infection, is developed early in the course of the malady, and ceases early. When the incubation period is short, the disease does not, as a rule, exhibit its effective power so soon, and there is a time, even after the complaint is declared, when the danger of communication is small. The rule, then, is: Long incubation, early, short-lived infection; short incubation, late and long infection. Exceptions prove the rule; hence, there is always a possibility of variations."

The subject of the prevention of the spread of contagious disease divides itself into (1) what may be accomplished by the attending physician, and (2) what may be attempted by the State or municipality. To the physician himself the subject is beset with difficulties, as ideal home conditions are not often found. In a private house it is well to place the patient on the top floor, where complete isolation from the rest of the family may be comparatively easy. Having isolated the case, the virus must be destroyed at its source, according to the nature of the disease, and not be allowed to disseminate itself. All superfluous articles should be removed from the room, and a sheet wetted with some disinfecting solution may be tacked over the doorway. While it is not contended that a sheet occasionally so wetted is a germ-proof barrier, it yet serves a purpose in more completely shutting in the sick room, and serves as a sort of danger signal to those without. The nurse should not mingle with the members of the family, and when she leaves the house for fresh air should change her clothing before going out of the room. The details to be observed in each case vary according to the nature of the disease. The room should be kept warm enough to allow a constant supply of fresh air to be procured by dropping one of the windows a little from the top. This will not only have a favorable effect on the patient by diminishing the chances of his own reinfection, but it will lessen the risks to the attendant. The greatest difficulty is met with in small apartments and tenement houses where the rooms are few and open into one another. Where the mother of the family has to do all the work she should have a loose wrapper to draw on in the sick room, which may be discarded on her exit. It is better to have the patient on a cheap cot which can be afterward thoroughly cleansed or destroyed, rather than upon a bed or sofa which will be difficult to free from germs. Any discharges from the nose, mouth, ears, or skin should be collected upon rags, or cheesecloth, which should at once be burned. This valuable precaution can easily be taken in the most restricted apartments, and yet is often neglected.

The question of when to allow a convalescent patient to mingle with others without the fear of infection is an exceedingly difficult one to answer, especially in the case of diphtheria. The Klebs-Lœffler bacilli may remain in the throat, as is well known, for months after even a mild attack. I have, however, never seen a case in which infection followed such persistence of the bacilli. After the end of a week or two, particularly when disinfecting gargles are employed, it hardly becomes necessary to maintain the patient in quarantine.

The germs of many diseases, notably scarlatina and diphtheria, remain long dormant in apartments; hence the necessity for thorough cleansing and disinfection. All clothing, bed-linen, etc., that has been in contact with the patient can be soaked in the solution recommended by the New York City Board of Health, *i. e.*, sulphate of zinc, four ounces, common salt, two ounces, water, one gallon. This solution is cheap, and easily procured, and may be kept constantly standing in the room. Spoons, cups, and all feeding utensils can likewise be soaked in this solution, but all articles after being taken out must be subjected to thorough boiling. Quilts, comforters, pillows, etc., may be thoroughly shaken on the roof, and then exposed for hours to the fresh air and sunlight. The two latter factors form the most harmless, but complete disinfections that are known. The furniture, floors, walls, and ceiling may be washed with carbolic acid, 1–20, or corrosive sublimate, 1–1000. These two disinfectants frequently fail to be effective because of too weak solution. The same preparations may be used to flush out sinks and water closets, as it is best not to multiply solutions. If the walls are papered they may be rubbed down with stale bread crumbs, which, bacteriologists have taught us, collect the germs. The same may be done to the ceiling. With reference to sulphur fumigation, although bacteriologists state that the fumes of sulphurous acid do not destroy spores, it has always seemed to me well to employ this procedure when possible. It certainly has the effect of sweetening the air of the room, and some practical workers in boards of health think it does good. A free application of moisture in the room increases its efficacy. The thorough airing required after the combustion of sulphur in a room may be a not unimportant factor contributing to its good effect. An ideal way of disinfecting carpets and other articles consists in steaming, and in large cities there are facilities for this practice.

When a contagious disease invades a family living in a limited apartment where complete isolation is difficult, if not impossible, the well children should be removed, if there is any place to take them to, until the illness is over and the quarters have been disinfected. This, however, is just what cannot be done in the great majority of instances, as no one wishes to harbor these poor children. To meet this dilemma, a few years ago the Committee on Hygiene of the New York County Medical Society suggested that stations or refuges be established where such children could be housed until the sick at home had either recovered or been removed, and the domicile disinfected. Houses arranged for such purposes ought to contain dormitories, and private rooms for such as could afford to pay for better accommodations. If the city authorities could be induced to establish a few such houses in various sections under the control of the Board of Health, which would transport cases upon notice from a physician, a powerful agency in preventing the spread of contagious diseases would be established.

Probably the most powerful factor in the spread of contagious diseases among children is found in the public and parochial schools. The sanitary condition of these buildings in the poorer sections of the city is bad. All the elements favoring a spread of contagion are here found. The children are crowded together in small rooms that are very poorly ventilated. Not only is the ventilation defective, but the cubic air space allowed to each pupil is insufficient. In the three lower classes of the primary schools the prescribed allowance of space to each pupil is 70 cubic feet; in the three higher grades, 80 cubic feet; while in the four lower grades in the grammar schools the allowance is 90 cubic feet, and in the four higher grades, 100 cubic feet. The Board of Health requires that in tenement houses the allowance shall be 400 cubic feet, and in some cases, 600 cubic feet, to each person. Four hundred cubic feet are required for each lodger in the lodging houses in this city. With a low allowance of air space to each child there is no suitable way in the old buildings of letting out the exhausted air and letting in fresh air in its place. It is obvious that even with a generous allowance of cubic air space if there is no way of removing foul air a room crowded with children will soon become close and stuffy, and any poisons that may be generated will become active.

In my opinion, however, one of the most powerful factors in the spread of contagion in these schools consists in the arrangement of the wardrobes, and in the lack of proper places to hang wraps and cloaks. Some of the class-rooms have narrow wardrobes at the back, where the clothing is shut in; in others the clothing is hung directly upon hooks on the wall. In a few cases the back seats are used for this purpose. Damp and dirty outer clothing should never be kept in a school-room crowded with little children. If any of these articles of clothing are infected with germs of disease, especially scarlatina or diphtheria, all the adjacent garments are liable to become infected. Much care and thought should be spent on the best means of disposing of the outer clothing of children during school hours. Whenever possible proper drying and ventilating rooms should be provided. In the schools that house the poorest children, where the danger of contagion is greatest, the sanitary conditions are the worst, as the writer has repeatedly demonstrated.

That the schools are active agents in the dissemination of contagion is proved by a recent report of Dr. George S. Lynde of the New York City Board of Health. According to this report, epidemics of measles, diphtheria, and scarlatina were directly traced to certain schools. Thus, out of thirty-seven cases of measles investigated during three weeks last October, in a restricted neighborhood, thirteen were traced to a parochial school, two to a public school, and seven to a kindergarten.

Certain recommendations made by the Board of Health for application to these schools will do much good if carried out. Thus, the use of slates, slate-pencils, and sponges shall be discontinued. According to requirement, pupils shall be supplied with pencil and pen-holder, each pupil to retain those received in a box provided for the purpose, each box to be marked with the pupil's name. Pencils and pen-holders shall not be transferred from one pupil to another without suitable disinfection. All school property left in a school building by a child sick with any contagious disease, and all such property found in an apartment occupied by a family in which a case of smallpox, typhoid fever, diphtheria, scarlet fever, or measles has occurred shall be taken by the Health Department for disinfection or destruction. Books which are taken home by pupils shall be covered once each month with brown manilla paper. Places for drinking water on the ground floors of school buildings shall be discontinued, and a covered pitcher be provided for each class-room, in which fresh water shall be placed before every session. A numbered cup, to be kept in the class-room, shall be issued to each pupil, and no interchange of cups shall be allowed. The floors, doors and door-knobs, and the stairs and banisters of school-rooms shall be washed with washing-soda solution (half a pound of washing-soda to three gallons of water) at least once each week.

The Board of Education should require that all buildings hereafter constructed for use as school buildings shall be provided with sufficient closet space to accommodate without crowding the outer garments of all pupils attending the school, this closet space to be arranged so that it can be well and easily ventilated when full of garments, and that the ventilation be into the corridor or outer air, and not into a school-room. A recent undertaking of the Board of Health consists in having the schools under the observation of medical inspectors. Much good will doubtless be accomplished in this way.

MEMORANDA RELATING TO THE WORK OF THE MEDICAL INSPECTORS OF SCHOOLS.

1. It shall be the first duty of the teachers of the different classes in each of the public and parochial schools of New York City to select every morning from their pupils those who seem to be ill or not in good physical condition, or those whom they have reason to suspect have been in contact in their families, or otherwise, with persons suffering from contagious disease. These children shall be at once separated from the remainder of the class and sent to some room set aside for this purpose for examination by the medical inspector of the school. They shall be examined by the inspector immediately after the beginning of the morning session, and the respective teachers shall then furnish to the medical inspector any special information that they may have regarding their own pupils, and shall also leave with him each day a list of the absentees from their classes, with the cause for the absence, so far as known, and the addresses of the absentees, with the time that they have been absent from school.

2. It shall be the duty of the teachers in each class-room before re-admitting to school any child who has been absent for forty-eight hours or more because of illness, or for any other cause, to refer such child to the medical inspector for examination, furnishing at the same time such information as may be in his or her possession.

3. It shall be the duty of the medical inspector of schools to carefully examine all children separated by the teachers for any reason from the rest of the class, and all those who have returned to the school for re-admission. Every child who is found to be suffering from any contagious disease, such as scarlet fever, measles, diphtheria, whooping cough, mumps, chickenpox, smallpox, typhus or typhoid fever, and any contagious skin disease, or contagious disease of the eyes, or who is infected with body vermin, or who is too ill from any other cause to properly remain in school, shall be at once sent to its home.

4. The name and address of the child, with the record of the action taken, and the reason for it, shall be properly recorded, and a copy forwarded each day before 1 P.M., by mail, to the chief inspector of contagious diseases.

5. Any child sent to its home because of illness shall be furnished with a card, stating the facts, and instructed to present this card to its parents or guardians immediately on its return home.

6. If any child who has thus been sent home for contagious disease returns to school the following day, the same action shall be taken by the teacher and physician, and the chief inspector of contagious diseases shall also be notified, and a postal card with the facts relating to the case shall be mailed to the parents or guardians. Each medical inspector of schools shall forward daily to the chief medical inspector of schools a list of absentees furnished him by the various teachers in the classrooms, and a copy of his record book, showing what action he has taken during the day, and this shall be mailed in each instance not later than one o'clock of each day.

7. If any pupil is found suffering from any of the following contagious diseases—scarlet fever, measles, smallpox, typhus fever—and the pupil's home is at such a distance as to make it impracticable, or improper, to walk, the department shall be immediately notified and an ambulance, or conveyance, will be sent to remove the pupil to its home.

8. The medical inspector shall in every case where children are suffering from sore throat take a culture of throat secretions, and forward it at once, with the name and address, to the Division of Bacteriology. Where children have been excluded because of illness, before readmission to the school, the medical inspector shall make careful examination and question the pupil closely as to the nature of the illness, if information is not already at hand as to this, and shall, under no conditions, re-admit the child to school unless entirely freed from danger, and unless, in case of contagious disease, the child furnishes the proper school certificate.

9. The medical inspector shall be responsible for and shall supervise the disinfection of desks, seats, writing utensils, etc., of pupils who are absent from school because of contagious disease, and shall see to the proper disinfection of books.

10. The medical inspectors of schools shall be held personally responsible for the existence, or extension, of epidemics of contagious disease of any kind in their respective schools, and shall, in addition to the duties described, take all necessary precautions, and use all the means required, to obtain necessary information relating to the illness of pupils, and to the methods of extension of contagious disease in their respective schools.

Finally, the dispensaries of this city contribute very largely to the spread of contagious diseases, especially among children. This is a feature of the dispensary evil that seems to have escaped notice. Children having mild attacks of diphtheria, as well as scarlatina, measles, and pertussis, are first brought in public conveyances, and then allowed to sit among other children until the physician in charge discovers the nature of the malady. Very few dispensaries have proper waiting-rooms, or take efficient means to avoid this great evil. It is a good subject for investigation by the Board of Health.

SPLITTING THE KIDNEY CAPSULE FOR THE RELIEF OF NEPHRALGIA.

By GEORGE BEN JOHNSTON, M.D.,
OF RICHMOND, VA.;
PROFESSOR OF THE PRACTICE OF SURGERY AND CLINICAL SURGERY IN THE MEDICAL COLLEGE OF VIRGINIA; SURGEON TO THE OLD DOMINION HOSPITAL.

PAIN in the kidney usually denotes a gross lesion, the character of which is indicated by other manifestations. Hydronephrosis, cystic disease, and impacted calculus, are the least painful of the surgical diseases of the kidney. On the other hand, pyonephrosis, suppurative nephritis, perinephritis, perinephritic abscess, tubercular disease, and tumors, and calculi in the pelvis of the organ, commonly produce severe pain. The presence of pain in the kidney aids in locating the site of the lesion. A glance at the known distribution of the nervous supply shows that the pelvis and capsule are sensitive, whereas the parenchyma is singularly insensitive, as evidenced by its ability to undergo complete destruction, without pain, while the most trivial injury to or irritation of the pelvis or capsule will provoke violent pain. We infer, therefore, that when pain is a pronounced symptom in any lesion of the kidney, the pelvis or capsule is encroached upon.

In any of the conditions I have mentioned, where pain is a symptom, there are other symptoms and physical signs concomitant with pain, which usually enable the surgeon to determine the nature of the malady. Occasional cases are encountered, however, in which pain is the most prominent symptom, and where no physical signs or urinary changes exist to lead to a conjecture that organic changes are taking place in the kidney. Collateral organs are frequently involved in this pain, such as the bladder, penis, and testicle. Such cases simulate a condition involving a demonstrable lesion, such as renal calculus, vesical calculus, and the like. Scrutinizing and repeated examinations fail to verify such an assumption, for the urinary changes and physical signs ordinarily associated with the suspected lesion are absent. I know of no condition of the pelvis provoking sufficient pain to call for surgical investigation that would not afford abundant evidence of an inflammatory or mechanical injury competent to account for the existing pain. Such is not true of pain arising from an irritation of the surface of the kidney or its capsule. Here, violent pain may exist, with complete disassociation of all other evidences of kidney disease.

Medical literature contains reports of many cases operated on for renal calculus where no stone was found, but where symptoms subsided after operation. Here, the pain which caused a simulation of calculus was due to some obscure and undemonstrable lesion and was relieved by splitting the capsule in searching for the stone. The capsule may have been contracted, the kidney tissue swollen and tense, or some other state existed which caused irritation of the sensory nerves of the capsule, producing the misleading pain without any actual structural change in the tissues themselves. I am constrained to believe that such cases are not altogether rare. I have seen reports of two such, and three others have been reported by Dr. L. M. Tiffany of Baltimore. Two of these were included in a paper read by him before the American Surgical Association, and published in its Transactions for 1889. The third, in a patient of Dr. Trimble of Baltimore, the report of which was communicated to Dr. Tiffany, and a fourth, which I reported to him, were incorporated in his paper on "The Surgery of the Kidney," read before the same society, and published in its Transactions for 1894.

Case I.—The first case that I wish to report was referred to me by Dr. W. H. Barham of Southampton Co., Va. The patient came with the diagnosis of probable stone in the kidney. He was a man, twenty-six years of age, a farmer by occupation, slender, and pale, and his health had never been robust. At the age of ten he had had a painful attack resembling renal colic, and another some two years later. Ten years previously to my seeing him he began to complain of pain in the right loin. This pain soon grew so severe and constant as to incapacitate him from his routine work. Besides this incessant pain he had some paroxysms of excruciating pain apparently in the right kidney, extending down the ureter, which resembled renal colic. At these times there was some retraction of the testicle on the right side, and very frequent urination. No stone was ever passed. He likewise suffered pain in the bladder. At the time he presented himself to me he was in the habit of inclining the body forward and to the right when standing or walking, so as to relax muscular pressure on the kidney. When he laid down, he flexed the thighs on the abdomen for the same purpose. It required several minutes for him to rise from recumbency. All of his movements were characterized by the greatest deliberation and slowness, and all looked to the protection of his right kidney. Palpation revealed the right kidney slightly enlarged, somewhat firmer than its mate, and exceedingly tender. He winced perceptibly when bi-manual pressure was made on it.

Up to this point his history was identical with that of nephrolithiasis. Careful and repeated examinations of the urine alone furnished a peg on which to hang a doubt. In cases of stone in the kidney, the urine presents the following characteristics: There is nearly always some hematuria. When blood is passed the amount is usually not large, but is generally constant, and is increased by exercise; it is intimately mixed with the urine, and gives to it a smoky brown color; the urine is highly acid and usually diminished in quantity; pus is always present, but may be very small in quantity, due to simple irritation. If infection of the kidney occurs, the amount of pus is greatly increased. Epithelia from the pelvis of the kidney can be made out by microscopic examination. Crystals of the salts that are in excess, and which probably compose the calculus, are usually present; occasionally portions of the calculus are passed. None of these conditions of the urine was ever present in this case. The urine was absolutely normal. Thus I was forced to the belief that no stone existed, or if one was present, that it was imbedded in the substance of the kidney and was not free in the pelvis. I regarded it as a case of nephralgia simulating stone. Nevertheless an exploratory operation was demanded.

I placed the patient face downward on the operating table as being the best position to facilitate exposure of the kidney by incision. The Edebohls cushion was put under his dependent side, and the illiocostal space of the afflicted side thus elongated. An incision was made along the outer border of the erector-spinæ muscle, commencing just below the last rib, carried to near the crest of the ilium, and deepened until the perirenal fat was reached. This was torn through and the kidney exposed. A few sweeps of the finger were made around the kidney to free it sufficiently to permit its partial delivery through the wound. Inspection showed the kidney to be somewhat enlarged and the capsule mottled. Palpation revealed a firm, tense, and unyielding condition of the organ, but nowhere was there a hard mass such as would be produced by a stone. The thumb and finger compressed the pelvis between them and nothing except the pelvis and upper portion of the ureter separated them. No foreign body could be felt. The ureter for a short distance was also palpated and found to be free from obstruction. To make the search complete I took a slender, sharp, round needle and passed it into the kidney at many points, so that if a stone were present it could be detected when the point of the needle impinged upon it. Nowhere did I find a stone, but from every puncture the blood spurted freely and to a considerable height. This diligent and thorough search served to eliminate the possibility of a foreign body being present, and confirmed the diagnosis of nephralgia.

I considered the symptoms in this case as arising from a too tight capsule, and I therefore split the capsule from one end of the kidney to the other, and penetrated a little way into the kidney substance as well. This done, the cut margins gaped widely apart, and the kidney tissue bulged into the incision. I placed a rubber drainage tube in the wound, closed it with deep sutures of silkworm-gut, and dressed it with iodoform gauze. The patient made an easy and uneventful recovery. The pain began to diminish almost immediately, and when he was discharged from the hospital he had been absolutely free from pain for more than two weeks, and was otherwise much improved. A letter received from Dr. Borham several months later said: "The man is entirely well. He has had no pain since his return, has gained more than twenty pounds in weight, and has worked every day during the season in the harvest field."

CASE II.—J. S., of Irish birth, sixty-five years old, carpenter by trade, consulted me in September, 1891. In early life he followed the sea. Had yellow fever in 1850, in Colon, C. A. Ten years ago he was operated on for piles, by ligature, and cured. He had had no other serious sickness, and was temperate in his habits. For some weeks he had suffered from pain in the right loin. It was variable in intensity, but always present, and at times was exceedingly severe. Associated with it were gastric disturbances, irritability of the bladder, and now and then retraction of the right testicle. Frequently the pain followed the course of the ureter, and was occasionally felt in the glans penis. There was tenderness on pressure over the kidney. The assuming of an attitude which relaxed the muscles of the right loin brought some relief. There was some vesical irritation—enough to justify the sounding of the bladder, but this produced negative results. The desire to pass water was quite marked. There was no blood or pus in the urine. Frequent and painstaking examinations of the urine were made, both by me and Mr. Hugh Blair. These examinations, to a certain extent, bore out the opinion I had formed of the case, namely, that I had to deal with a renal calculus. When I became convinced of this, nephrolithotomy was determined on. The operation was performed November 25, 1891. It was conducted with the usual aseptic precautions. The incision by which the kidney was exposed was V-shaped, with the apex upward. On exposure, the kidney appeared larger and firmer than I have usually seen it. Palpation revealed nothing. Numerous punctures with a needle failed to detect the presence of a stone. Through each of the little wounds made with the needle a smart little geyser of brilliant blood welled high up, and the punctures continued to bleed freely. Being convinced now that I had proceeded on an erroneous diagnosis, and recalling reported cases of "capsule-splitting" for painful kidney, I resolved to practise this procedure here. Consequently, a free slit was made in the capsule the whole length of the kidney. This wound gaped widely and the kidney tissue bulged far out. Immediately the bleeding from the needle punctures ceased. A small drainage-tube was inserted, and the flesh and skin wounds carefully closed.

On the evening of the day of operation, after the effects of the anesthetic had entirely passed off, the patient expressed himself as feeling much relieved. His recovery from the operation was wholly satisfactory. The symptoms simulating calculus disappeared. The pain promptly abated, and never returned, and with its disappearance the other distressing symptoms likewise subsided.

CONCLUSIONS.

1. Nephralgia is not always associated with a demonstrable lesion.
2. When other evidences of kidney disease are wanting, the pain is perhaps due to a too-tight capsule.
3. Nephralgia may, and frequently does, simulate symptoms of gross tissue changes or presence of mechanical irritants.
4. When severe and persistent pain in the kidney exists, without other evidences of renal involvement exploratory operation is indicated.
5. When inspection, palpation, and needle punctures fail to disclose a condition sufficient to account for the pain, the capsule should be freely opened.

CLINICAL MEMORANDA.

A CURE BY HYPNOTISM.

BY WILLIAM ARMSTRONG, M.D.,
OF NEW YORK.

THE editorial in THE MEDICAL NEWS of October 31, 1896, pointed out the limited use of hypnotism and the possible injury to the subject by "diminishing his power of self-conscious coördination and direction of effort." Unquestionably this danger is a serious one, and should always be borne in mind by those who practise this method of cure. I am convinced, however, that one occasionally meets with a case of hysteria in which tonic treatment, both physical and mental, proves ineffectual, and the final resort to hypnotism is justifiable. Certainly the general tonic treatment should always be tried first, and tried thoroughly, and the indiscriminate employment of hypnotism as a panacea is to be vigorously condemned.

I submit the following case, in which I am satisfied that hypnotism cured the patient and was in no wise productive of harm:

R. F., aged twenty years, married, and the mother of a child two years old, presented herself to me in May, 1895. She said she had always been well and strong until eighteen months previously when she began to have headache and knocking sounds in her head above the left ear. This headache and knocking had persisted, night and day, for the entire eighteen months, without a moment's cessation, preventing sleep and causing great suffering. She had been steadily losing flesh, strength, and appetite during this period. After her family physician had exhausted his skill in tonic treatment, she had gone to a hospital, where she spent about a month, but with absolutely no relief. She had consulted several specialists, but they only advised general tonic treatment. No specific or malarial history was obtainable.

I found her to be a slight woman, pale and nervous, with all of her tendon reflexes slightly exaggerated. The knocking sounds in the head were apparently rhythmical, but less frequent than the pulse. The physical examination was otherwise negative, as was also the urinary analysis. Examination of the blood revealed eighty-five per cent. hemoglobin.

For several weeks she was given general tonic treatment, but without the first sign of improvement. She ate scarcely anything, and slept only four or five hours out of the twenty-four. I finally resorted to hypnotism. While in the hypnotic state she was told that the headache and knocking had disappeared. Upon awakening she announced with glee that she was entirely free from headache (for the first time in eighteen months!); the knocking, however, persisted. Ten hours later the headache returned with its usual severity. At the next *séance* she was told that the knocking had shifted to the right side of the head, which suggestion was adopted when she awoke. By this time I felt reasonably sure that her troubles were purely hysterical, and determined to make a thorough test of the efficacy of hypnotism as a curative agent. I found, by several trials, that I could not keep the headache away longer than nine or ten hours. I therefore began by hypnotising her three times a day, at intervals of eight hours, making the evening hypnotism after she had retired. In this way she soon fell into the habit of sleeping seven or eight hours every night, which habit was maintained throughout the rest of the treatment. At the same time she was put upon iron and strychnin, and insistance was made that she should eat three good meals a day and take a moderate amount of exercise in the open air. After a week of this treatment, during which time she was entirely free from headache, the hypnotism was applied only twice a day for ten days, then once a day for two weeks, then every other day for a month, and so on, gradually lengthening the interval until, at the end of six months, she was being hypnotised but once in two weeks. The treatment was then stopped. The idea of the cautious lengthening of the interval was to retain the confidence of her sub-consciousness. Had the suggestion been made early in the treatment that the headache would remain away for any great length of time, her confidence in the prediction might not have been great enough, and ground lost instead of gained. As it was, the confidence steadily increased with time. Such, at least, was the theory on which I worked, and it would seem to have been borne out by my experience. Every time that the interval was lengthened there was a slight return of the headache at first, but she soon adapted herself to the change. It was not until the third month that I succeeded in ridding her of the knocking sounds in her head, after which there was no recurrence. During the first three months of treatment she gained twelve pounds, and her appetite and color returned. It is now just a year since she was last hypnotised, during which time she has been absolutely free from the headache and the knocking. She is in excellent health, and there is no indication of nervousness or lack of self-control.

A CASE OF IMPERFORATE ANUS; INGUINAL COLOTOMY.[1]

By FRANCIS H. STUART, M.D.,
AND
J. C. BIERWIRTH, M.D.,
OF BROOKLYN, N. Y.

Anna May B. was born at the Low Maternity. Brooklyn Hospital, on June 4, 1895. Since the second day after birth the baby had shown signs of gastro-intestinal trouble, with restlessness, vomiting of food and bilious matter, and gradually increasing tympanites and marked abdominal distention. The superficial abdominal veins were very large and full. Only one stool had been reported since birth. A quarter of a grain of calomel, followed in half an hour by a dram of castor oil, was administered without result. The rectum was then examined and found to be occluded about one and one-quarter inches above the anus. A search with an ordinary probe did not reveal an opening. Examination per vaginam resulted negatively as far as presence of rectum was concerned, and inguinal colotomy was decided upon. A straight incision one and one-half inches long, parallel to and about one inch above Poupart's ligament, was made. On separating the peritoneum the upper part of the sigmoid flexure and a small mass which greatly resembled the appendix vermiformis appeared in the opening. The latter was pushed back, and the angles of the wound were closed with iron dyed silk sutures. The gut was attached to the edges of the wound with continuous sutures of the same material, and afterward incised. As soon as the gut was opened there was a discharge of gas and meconium in large amount, which greatly relieved the distention of the abdomen. The wound was dressed with iodoform gauze.

During the morning of June 8, four days after the operation, the adhesions and sutures gave away, causing the gut to be pushed out of the wound for about two and one-half inches. Anesthesia was produced, the gut was cleansed with a bichlorid solution 1 to 1000, the edges were freshened, and the angles of the wound closed, and the gut attached to the edges of the abdominal wound, fourteen interrupted catgut sutures being employed. Abdominal support of adhesive plaster was applied, and the wound dressed with sterilized gauze and aristol. The child rallied well.

On June 26, the baby was anesthetized for examination and with the view of possible operation. Upon introducing a bullet-probe through the artificial anus, the gut was found to extend about three-quarters of an inch below this opening and to end in a cul-de-sac. The probe could not be felt through the vagina, although this canal admitted the whole of the little finger. The lower pouch was found to have contracted since it was last examined (day of first operation), and measured about three-quarters of an inch in length. On these findings operation was deferred.

On June 30, the artificial anus was of such size as to admit the tip of the little finger, had fair contractile power, and was free from erosion and inflammation. Around it were a number of radiating suture-scars. The patient apparently had some power of retaining feces. August 12, being then two months of age, she was transferred to the surgical ward of the Brooklyn Hospital under the care of Dr. Bierwith.

---

[1] Reported to the Kings County Medical Association, Brooklyn, May 14, 1896.

OPERATION BY DR. BIERWITH.

The patient was first seen by me on the first of September, and then presented the following conditions: At the site of the inguinal opening the colon was prolapsed and invaginated in two sections, the lower end about four inches and the upper end about two inches. There was an imperforate anus ending in a blind pouch about one and one-quarter inches in depth from the sphincter. The prolapsed and invaginated portion of the gut showed numerous small ulcerations, was much congested, and bled freely upon touch. The bowel could be reduced without difficulty.

The first operation for the relief of the imperforate anus was done October 15, 1895, chloroform being used as an anesthetic. The operation consisted in pulling down the blind pouch, securing it by two silk sutures outside, which were given to an assistant to hold, and opening it sufficiently to admit the little finger; then the invaginated lower portion of the gut was reduced into the abdomen and its blind end pushed by means of a large gum-elastic bougie toward the anal opening and likewise secured by two lateral silk sutures which were held by the assistant. Then the upper pouch was opened and by means of Lembert sutures united to the opening of the lower pouch. After this, the bowel was flushed from the inguinal opening down through the anus and was found to be entirely patent. Although there was considerable depression from the chloroform-narcosis, the child rallied well on the following day and had no rise of temperature. The bowel was washed through twice daily, and the child fed on easily digested food. October 21st, six days after the operation, the union was found to be perfect between the two ends of the gut, showing an annular constricting band about one inch from the sphincter. This was ordered dilated gently with a well lubricated finger once each day. The bowels continued to move through the inguinal opening.

On November 1st, the first operation to close the abdominal opening was done. I thought this might be accomplished by splitting the skin all around the opening, allowing the bowel to remain attached, and sewing the two parts separately (that is, approximating the edges of the gut), and then by deep sutures to bring the edges of the skin together. I adopted this procedure in order to avoid opening into the peritoneal cavity. On November 3d, the bowels moved per anum. During the night of November 4th the child had a continuous attack of coughing. In the morning some fecal matter was forced through the abdominal opening. November 5th, all the stitches had given away and there was again complete prolapse and invagination of the gut as before the operation. The failure of this operation was due primarily to the hard cartilaginous edges of the wound in which the stitches could not hold, and to the unfortunate severe attack of coughing.

On November 12th, I performed the second operation for the closure of the abdominal opening. This time I concluded to dissect the gut out and away from its cutaneous attachment, taking it outside of the abdomen, freeing it from all cicatricial tissue, and closing the opening transversely by Lembert sutures. This was done without difficulty. Next, the skin-wound was freed of as much of its cicatricial tissue as was possible and then united by deep and strong silk sutures. There had been so much loss of substance that the edges were approximated with the greatest difficulty and the sutures in places considerably constricted the tissues. The operation was of necessity a long one, occupying nearly two hours. The child reacted very poorly from the chloroform, and for several hours I was in doubt whether it could rally. On the following day, in the morning, the temperature rose to 103$\frac{2}{5}$° F., but in the evening of the same day it fell again to 99$\frac{1}{5}$° F. The child had rallied well from the operation, had a good pulse, and took nourishment fairly well. The morning elevation of temperature continued for several days (until the 16th), after which date it remained normal. On November 15th there was some sloughing around the edges of the wound at the points of the tight sutures. The bowels moved per anum for the first time two days after the operation and regularly every day after that. At no time was there any tympanitic distention. The skin wound finally healed by granulation at the places where the sloughing had taken place and the child made an uneventful recovery. The anus was dilated every day by the aid of the finger. The child passed from my observation after November 22d, and the history from that time until discharged, February 19th, is extremely meager. I was told by the house surgeon of the Brooklyn Hospital that considerable difficulty was experienced in finding a proper nourishment for the child, and I suggested modified cow's milk approximating as nearly as possible mother's milk. The child thrived very well on this and gained rapidly in flesh. Some time in the beginning of February, several small abscesses made their appearance, one of considerable size being on the scalp, which I lanced at my office on February 19th. The child was then in a very miserable condition, being poorly nourished, and white and pasty looking. She was readmitted to the hospital on February 28th, with a diagnosis of general furunculosis, and died from general marasmus on April 20th.

We were fortunate to obtain an autopsy on the case, which was performed by Dr. J. M. Van Cott, Jr., Pathologist to the Brooklyn Hospital. Aside from the general evidences of malnutrition in all the organs of the body, nothing abnormal was found except a fecal concretion about the size of a pigeon's egg in the sigmoid flexure. The gut was taken out in its entirety, leaving the skin around the anus attached, and also the skin which contained the scar of the former abdominal opening. The gut was firmly adherent to the abdominal wall at this point. There was hardly a trace of a scar left in the gut at the point where the opening was made for the inguinal colotomy, and notwithstanding the poor condition and sloughing of the skin wound of the colotomy, there was but a trace of the scar in the skin attached to the gut. The line of union and its still existing circular constricting band between the two pouches of the rectum was very clearly shown. I may remark in parenthesis that the fecal concretion found in the sigmoid flexure in no way interfered with the action of the child's bowels which moved two or three times daily after the last operation.

This case is of interest chiefly from the fact that it demonstrates the great tolerance of surgical interference in infants of such tender age. The child was operated upon several times by Dr. Stuart, and at my hands she underwent three capital operations and rallied well from all of them. The case is of further interest in that we are able to show this specimen six months after the first operation, demonstrating the wonderful healing and recuperative powers of infantile tissues.

HOSPITAL REPORTS.

TREATMENT OF TYPHOID FEVER AT THE NEW YORK HOSPITAL.

BY HENRY P. LOOMIS, M.D.,
OF NEW YORK;
VISITING PHYSICIAN TO THE NEW YORK HOSPITAL.

THE Editor of the MEDICAL NEWS has asked me as one of the visiting physicians to the New York Hospital to explain in detail the treatment of typhoid fever employed there during the past year. In ninety cases admitted to the hospital from December 1, 1895, to December 1, 1896, mortality was reduced to less than ten per cent., the former average mortality in typhoid fever, as given by Murchison, being rated at from ten to thirty per cent. It is fair to assume that the rigid system of hydrotherapy, carried out according to the methods of Brand, is to a great extent responsible for these results. The line of treatment adopted may be considered, for better understanding, under certain general heads, as follows:

GENERAL MANAGEMENT.

The patient is confined to bed in a recumbent position and remains there until convalescence is established, never being allowed to sit up. His clothing, with the exception of a linen shirt, is removed. A sheet is used for covering, and in cold weather a blanket is added. The bed is of woven wire with a soft hair mattress covered by two thicknesses of blankets. Bed and body linen are changed daily. Whenever blankets, sheets, or rubber covers become soiled they are removed at once, a nurse and orderlies being in constant attendance. All sheets and other articles that have been in contact with the patient, before being sent to the laundry, are soaked for an hour in a 5-per-cent. carbolic acid solution. The feces as soon as passed are mixed with a 2-per-cent. solution of bichlorid of mercury and allowed to stand an hour. Separate glasses and dishes are set aside for all typhoid fever patients. The nurses and orderlies who give the baths are required to carefully wash their hands with soap, and then with a bichlorid of mercury solution, after serving the patient.

Mouth.—The distressing condition of the mouth and nasal passages, of which so many patients complain, is relieved by a mild solution of some aromatic antiseptic, such as tincture of myrrh, ʒi; sodium bicarb., gr. 20; water, ℥vi. For the dryness of the mouth, dilute phosphoric acid solution is used in many cases (ʒi of the acid to ℥viii of water). A spray of Dobell's solution is used for the nose, and adds much to the comfort of the patient.

Diet.—As soon as the patient is admitted to the hospital he is put upon a milk diet; ordinarily ℥viii of cold milk with a little water added is given every two hours when the patient is awake. Mutton or beef broth is substituted for the milk, three or four times a day. When there is nausea or vomiting, the milk is peptonized; if this fails to control the nausea, oxalate of cerium, gr. v, and bicarbonate of soda, gr. x, are added to each glass of milk. Sometimes pancreatin, gr. iii, and sodium bicarbonate, gr. x, are substituted for the above. In some cases, good results have been obtained by adding gr. v of bismuth to each glass of milk. Ordinary nausea will be controlled by following out these suggestions. If it should not, small doses of morphin or codein may be given. Sips of champagne in obstinate cases will give temporary relief. It is often necessary to reduce the quantity of food and give only one or two ounces every hour until the vomiting is controlled.

Stimulation.—When the condition of the pulse, and the dry tongue, indicate cardiac failure, stimulation is commenced. This often is not until the end of the second week. Many cases pass through the whole course of the disease without any stimulation. When necessary the amount of whisky is increased until from eight to twelve ounces is taken during twenty-four hours. This is generally administered every three hours in ½-ounce doses, diluted with water. Whisky is the only form of alcohol generally used, and when necessary, it is supplemented by sulphate of strychnin in $\frac{1}{30}$ grain doses, ordinarily once in four hours.

TREATMENT OF FEVER.

The routine antipyretic treatment consists in the giving of tub baths. The temperature of the patient is taken every three hours, with the exception of the hours nearest midnight, when it is usually omitted if the patient is asleep. A tub bath of ten minutes' duration is given whenever the temperature reaches 103° F., or above. The water for the first bath is at a temperature of 80° F., for the second 75° F., and for the other baths 70° F.

The patient is lifted by two or more orderlies into the bath, the head being supported while in the bath by a rest which is usually a piece of bandage spread across the tub. The patient's ears are closed with cotton, and while in the bath, ice-water is frequently poured over the head. Two attendants rub the patient gently over his entire body while in the bath. As soon as he is lifted out, and placed upon the bed, which has been freshly made, the patient is wrapped in a sheet and thoroughly dried; this sheet is then drawn aside and he is covered with one or two blankets, and hot-water bottles are placed at his feet.

He is left with just enough bed-clothing to keep him from feeling cold. Fifteen minutes before the bath half an ounce of whisky is given, and after the bath a glass of hot milk. Half an hour after the bath, temperature, pulse, and respiration are taken and recorded upon a chart. In mild cases (temperature below 103° F.), no attempt is made to reduce the temperature, but sometimes alcohol sponge-baths are given for their quieting effect. The tub-baths are are discontinued only under the following circumstances: (1) When hemorrhage, no matter how slight, occurs from the bowels; (2) when peritonitis develops; and (3) when, in exceptional cases, the tub-baths do not seem to act well, either on account of the poor reaction of the patient, as shown by the pulse and the capillary circulation, or on account of their nervous effect, the dread of the baths being apparently so real in some cases that any benefit to be derived is questionable. Neither bronchitis nor pneumonia are contra-indications for the use of the bath. When the baths are stopped a rubber coil, through which ice-water constantly passes, is kept upon the abdomen. When it is necessary to use the coil, I have personally found that five grains of antefebrin, four or five times a day, will keep the temperature much lower than when the coil is used alone.

The benefits noticed from the use of the baths are: (1) Reduction of the fever; (2) slowing of the pulse, and an improvement in its quality; (3) quieting of the patient and the lessening of insomnia (the patient generally falls asleep immediately after the bath); (4) improvement in mental condition (delirium) and lessening of muscular twitchings.

TREATMENT OF SPECIAL SYMPTOMS.

Tympanites.—When this becomes distressing the diet is modified according to the suggestions given in the treatment of nausea and vomiting. Often when beef-juice is substituted for milk the abdominal distension will become less. Turpentine stupes are applied to the abdomen, and turpentine is given in 10-drop doses in capsules. When the larger bowels are distended with gas, a rectal tube is inserted from eight to eighteen inches and left in the bowel from half an hour to an hour. This is done three or four times a day.

Diarrhea.—It is not necessary to interfere with a moderate diarrhea, but when it becomes severe, and the patient is having more than four movements daily, the quantity of milk is first reduced so that the patient receives from 4 to 6 ounces every two hours. If this does not relieve the condition, subnitrate of bismuth is given, 10 or more grains per day. The bismuth alone will generally control the diarrhea, but if it does not, Dover's powders may be added.

Constipation.—Only during the first ten days of the disease will constipation be relieved by medicine, and then calomel is given in $\frac{1}{10}$ grain doses every hour until a grain has been taken. If this does not act, Rochelle salts are given the following morning. Later in the course of the disease glycerin suppositories and enemata are relied upon to control the condition.

Nervous symptoms.—In cases treated by cold baths, nervous symptoms are never a marked phenomenon, and sedatives are rarely needed. For the severe headache which occurs early in the disease, citrate of caffein, gr. 1, and acetanilid, gr. i to iv, in tablets, one every four to six hours, is given, and for restlessness at night, and insomnia, 5 grains of Dover's powder, repeated at the end of two hours, or trional, 10 to 20 grains at a dose, repeated if necessary.

TREATMENT OF COMPLICATIONS.

Hemorrhage.—If intestinal hemorrhage occurs, no matter how slight, all baths are at once discontinued, and the cold coil applied to the abdomen instead. The patient is kept absolutely still, and is not even turned on his side or moved in bed. At once $\frac{1}{8}$ to $\frac{1}{3}$ of a grain of morphin is given hypodermically, and then, for a day or two, $\frac{1}{4}$ to $\frac{1}{3}$ of a grain of opium is administered by the mouth every three or four hours. When the quantity of blood is excessive, and there is danger of heart failure, enemata of normal saline solution are given, a quart or two at a time, and these are repeated every four hours.

Peritonitis.—When peritonitis is due to perforation every patient has died within twenty-four hours. In one who recovered it is fair to assume that peritonitis was due to extension of inflammation from the intestinal ulcers, and was in every respect a local involvement. This patient was kept in a state of semi-narcosis by hypodermics of morphin for nearly a week, and at the same time turpentine stupes were kept constantly on the abdomen.

Bed Sores.—These rarely develop. Scrupulous cleanliness is the principal means employed to prevent them. The posterior part of the patient's body is carefully bathed three or four times a day with alcohol, and then dusted with a powder consisting of equal parts of starch and oxid of zinc. Sometimes bismuth has replaced the oxid of zinc. If the bed sores threaten to occur, an air cushion is used, or the patient is transferred to a water bed. When bed sores actually develop, they are dressed with iodoform, after irrigation with bichlorid of mercury (1 to 2000), or peroxid of hydrogen. This is done from one to three times a day.

Phlebitis.—This is treated by absolute rest and elevation of the limb. At first when the pain is intense the limb is enveloped in oakum, wrung out in hot water. Later, pressure is made on the limb by bandaging it with cotton bandages; often it is necessary for the patient to wear elastic rubber bandages for months after convalescence, to prevent swelling and pain in the limb.

Pulmonary Congestion.—When evidence of congestion appears an oiled-silk flannel jacket is at once applied to the chest. The patient is propped on his side, and, if indicated, the stimulation is increased. If a bronchitis of the smaller tubes develops, the application of dry cups to the chest, and the internal administration of carbonate of ammonia is resorted to. When inflammatory enlargement of the glands occurs, a dressing of a ten per cent. solution of carbolic acid is at once applied. As soon as abscesses form they are opened and drained. Satisfactory results have been obtained in some cases by aspirating the abscess, injecting with peroxid of hydrogen, and then allowing a ten per cent. mixture of iodoform and glycerin to remain in the abscess cavity.

RELAPSES.

Of the ninety cases under treatment, relapses occurred in five, or about five per cent. The percentages of relapses, given by different observers, ranges from three to fifteen per cent. In none of these did death occur. In each instance the fever was as high as in the original attack, but was of much shorter duration. The treatment employed was exactly the same as in the first attack, the baths being resorted to at once.

MANAGEMENT OF CONVALESCENCE.

The importance of attention to certain details during this stage of recovery cannot be overestimated. The question of food is the first one to be met. After the subsidence of fever, the patient quickly develops a ravenous appetite, and often begs piteously for a fuller diet. Solid food is never given before the seventh day after a normal temperature has been reached, and generally not until the tenth day. Dr. George Peabody, one of the visiting physicians, makes an exception to this rule and allows solid food as soon after the subsidence of fever as the patient desires it. A scraped beef sandwich, rice, or some other cereal are the first articles given, and these are very cautiously added to. The patient is not allowed to sit up until ten or fourteen days with normal temperature have passed, and never, if possible to prevent it, are friends admitted before the end of the first week of normal temperature. Many relapses have been traced to the excitement attending the visit of friends. In my opinion, this is one of the most important dangers against which to guard. The period of sitting up may be prolonged with the gradual return of strength. After four or five days, the patient is allowed to move about slowly, and then (by the end of a week), when the weather is fine, to take a short drive in the open air. Constipation during convalescence is treated by enemata. Upon the occurrence of diarrhea, the patient is kept in bed and the diet is restricted to milk for a few days. If this does not control it, bismuth is given. The distressing neuritis which often develops during convalescence is treated by wrapping cotton around the limb involved, in order to protect it from changes of temperature. Sometimes counter-irritation is applied by iodin, and a galvanic current given daily for ten minutes. In these cases strychnin is given, one-thirtieth of a grain after meals, until the neuritis disappears.

I am indebted to Dr. Williams, house physician of the New York Hospital, for the interest he has taken in the cases and for his assistance in the preparation of these statistics.

MEDICAL PROGRESS.

Tuberculous Esophagitis Secondary to Peribronchial Tuberculosis.—DANEL (*Journal des Sciences Médicales de Lille*, 1896, No. 22, p. 530) has reported the case of a woman, seventy-six years old, concerning whom little information could be gained, but who presented signs of pulmonary tuberculosis and bronchopneumonia inferiorly on the left. There were, besides, in the submaxillary region, on each side, several areas of superficial ulceration. Death resulting, *post-mortem* examination disclosed in addition to the accuracy of the clinical diagnosis the existence of ulceration of the mucous membrane of the posterior wall of the esophagus for a distance of nearly four inches. The floor of the ulcerated area was excavated, eroded, and of reddish hue, and at its margins and beyond numerous miliary granulations could be seen. Similar granulations in smaller number were present also on the anterior wall of the esophagus, the involvement of which extended almost as high as the pharynx. At the point where the esophagus crossed the right bronchus on its way from the trachea was a circular opening more than a third of an inch in diameter, establishing a channel of communication between the esophagus and a broken-down peribronchial gland. The stomach was dilated and slate-colored and contained a number of granulations, probably tuberculous. The intestine appeared to be free. The glands of the neck were enlarged, some being indurated and some softened.

Successful Gastro-Anastomosis for the Relief of Hour-Glass Contraction of the Stomach.—LAUENSTEIN (*Münchener Medicinische Wochenschrift*, 1896, No. 21, p. 491) reports the case of a woman, forty-three years old, who presented various symptoms of gastric derangement for a number of years, including vomiting, cardialgia, constipation, emaciation, and hematemesis. No physical evidences of disease could be detected, and examination with the tube disclosed signs of reduction in the size of the stomach. Operation was decided upon and when the stomach was exposed, after a median incision, an hour-glass deformity of this viscus was found. The lesser curvature was adherent to the under surface of the liver, and the constriction existed at this point. Communication was established between the two saccules by first suturing the peritoneal layer of the opposed surfaces posteriorly, then incising the seromuscular layer and suturing, and finally treating the mucous layer in the same manner. The opening was entirely closed by pursuing the same course anteriorly. Improvement at once resulted, with gain in weight and relief from previous symptoms. In a diagnostic way hour-glass contraction of the stomach is to be recognized by signs of diminution in the size of the stomach, *viz.*, distress after ingestion of small amounts of food or drink and intolerance of the usual quantity of fluid through the tube; the persistence of succussion-phenomena after apparent emptying of the stomach; the sudden appearance of gastric contents through the tube after the water returned in irrigation has been clear; and the evacuation of less water through the tube than was introduced.

Albuminuria during Pregnancy, Labor, and the Puerperium, and its Relation to Eclampsia.—As the outcome of a clinical investigation, conducted at the Institute for Midwives at Breslau, SAFT (*Archiv für Gynäcologie*, B. 51, H. 2, p. 207) found albuminuria present in 5.41 per cent.

cases of pregnant women, appearing in the second half of pregnancy, and increasing in frequency toward the close. The proportion of albumin present in the urine may reach a considerable degree several weeks before the termination of the gravidity. The frequency of albuminuria is greater among primigravida (5.9 per cent.), than among multigravida (4.1 per cent.). The degree of albuminuria during labor corresponds in general with the amount of albumin present in the urine during pregnancy. The frequency of albuminuria during parturition, as well as the degree, is greater among primiparæ (32.08 per cent.) than among multiparæ (22.6 per cent.). The albuminuria disappears generally during the first days of the puerperium, and only exceptionally is protracted over a longer period. This period is longer among primiparæ than among multiparæ. The renal lesion following pregnancy is more intense among the former than among the latter. The presence of white and red blood corpuscles in the urine of pregnant women free from albuminuria is attributable to lesions of the bladder. Tube-casts were found in the urine of pregnant and parturient women only in association with albumin. The appearance of tube-casts under such circumstances is independent of the amount of albumin, and their presence is without influence upon the duration of the albuminuria. Pregnancies and labors in cases of twins and hydramnios favor the occurrence of albuminuria. The contracted pelvis favors the occurrence of albuminuria in primiparæ, during pregnancy as well as during labor; in the case of multiparæ only during labor. Albuminuria is frequently the cause of premature labor. The kidney of pregnancy represents a condition due solely to pregnancy, never giving rise to pronounced disturbance to the general condition, and disappearing rapidly during the puerperium. It is thus in no way related to true nephritis. The pathologic-anatomic alterations of the kidney of pregnancy are essentially degenerative in character. The prognosis of the uncomplicated kidney of pregnancy is favorable; the danger of transition to chronic nephritis is insignificant. On the other hand, the prognosis of the kidney of pregnancy, attended by complications (such as nephritits or cardiac disorder), is dubious. The cause of the kidney of pregnancy is probably an auto-intoxication of the organism through some product of tissue-metamorphosis, which probably induces also the so-called molimina graviditatis and various nerve irritations. During parturition a new injurious factor is added in consequence of the muscular strain. In the presence of an excess of this poisonous product eclampsia results. The changes in the kidneys, liver, and other organs, are secondary to the eclampsia.

THERAPEUTIC NOTES.

A Better Method of Administering Castor-oil.—In the *Rev. de Therapeut. Médico-Chir.*, November 1, 1896, KLEIN mentions a method of overcoming the bad taste of castor-oil by simply warming it in a glass of milk and shaking it to an emulsion. The bad taste disappears and, owing to its finely divided condition, it acts more energetically, so that a smaller dose suffices, a half-ounce purging most adults. A small amount of sirup of bitter orange may be added if a flavor to the dose is desired.

Formaldehyde in Combination with Starch and Casein.—Formaldehyde vapor acting upon gelatin produces a substance called formalin-gelatin, the antiseptic action of which, in the treatment of infected wounds, has already been commented upon. Similar preparations, in which the substances affected by the formaldehyde vapor are starch and casein, have been the subjects of experiments. Like formalin-gelatin, they possess a mild antiseptic action, and tend to diminish pus-formation. BOHL reports in the *München. Med. Woch.*, No. 38, 1896, his experience with formaldehyde-casein.

A Contribution to the Study of Mixed Anesthetics.—LANGLOIS and MAURANGE (*Bulletin de l'Academie de Médicine*, No. 42, 1896), from observation of 350 cases, conclude that:

1. The combination of morphin and spartein, administered subcutaneously, stimulates and regulates the cardiac contractions.
2. After such injection narcosis is rapidly accomplished and easily maintained, with a minimum of anesthetic, for at least one hour,
3. In cases anesthetized for two hours or longer, although respiration becomes enfeebled, the heart-action continues forcible.

A Clinical Report on Analgene.—In the *Bull. de l'Academié de Méd. de Paris*, November 10, 1896, MONGORVO of Rio Janeiro presents the results of his experiments upon children with the new coal-tar product, analgene (ortho-ethoxy-anamonobenzoyl-amido-quinolin), obtained by Vis of Freiburg. It is claimed that this remedy possesses the analgesic, antithermic and sedative properties of antipyrin, thallin, phenacetin, antifebrin, etc., with none of their disagreeable and sometimes dangerous effects.

Mongorvo used the drug exclusively among children, and reports fifty-nine cases, thirty-three being various manifestations of malarial poisoning. Of these latter, the ages of the patients ranged from twenty days to thirteen years. The dosage varied from 25 centigrams to 3 grams in twenty-four hours. In no case did he observe the slightest unfavorable action upon the respiration or circulation. When large doses were given for some time the urine became colored a deep yellow or red, but albumin or sugar was never present. Its action in the malarial cases was prompt and efficient, reducing the temperature and shortening the period of the disease.

The twenty-six other cases comprised tuberculosis, lymphangitis, arthrosynovitis, parotiditis, Potts' disease, hip disease, epilepsy, hysteria, chorea, otalgia, herpes zoster, urticaria, and painful tumor of the liver. In all these the remedy acted well in reducing high temperature, when present, and allaying pain. It also influenced favorably the nervous phenomena present in the cases of hysteria, chorea, and epilepsy. The drug is soluble in slightly acidulated water and, as it has no taste, is well adapted for administration to children.

THE MEDICAL NEWS.

A WEEKLY JOURNAL
OF MEDICAL SCIENCE.

COMMUNICATIONS are invited from all parts of the world. Original articles contributed *exclusively* to THE MEDICAL NEWS will after publication be liberally paid for (accounts being rendered quarterly), or 250 reprints will be furnished in place of other remuneration. When necessary to elucidate the text, illustrations will be engraved from drawings or photographs furnished by the author. Manuscripts should be typewritten.

SATURDAY, JANUARY 30, 1897.

INSPECTION OF THE NEW YORK CITY SCHOOLS.

THE Board of Health of New York city is a model institution. In times of threatened epidemic it has risen to the occasion in such a way as to compel the admiration of every citizen whose health it aims to guard. The result is that no serious epidemic has for a long time been allowed to develop or prevail in territory over which it has jurisdiction. That it is ever on the alert to coöperate with the physician in combating infectious disease when it does exist is shown by its recent attitude on the subject of the serum diagnosis of typhoid fever.

Recently it has proposed a plan for the more prompt recognition and more effectual prevention of the common infectious diseases of children, particularly diphtheria, scarlatina, and measles. The plan is to have the children of the public and parochial schools inspected daily by a corps of physicians appointed and salaried for that purpose. To accomplish this the annual sum of $47,500 has been granted by the Board of Apportionment.

It is a fact apparent to every practising physician that the centers for the dissemination of the communicable diseases are the public schools and the public dispensaries, one being equally iniquitous with the other. The proof recently furnished by the report of a member of the Board of Health staff who was detailed to investigate the subject of the spread of disease by the public schools, is corroborated by the experience of every physician who is called upon to treat the children attending these institutions. In this report it is shown that it has been no uncommon experience to find that children absent from school had scarlatina, measles, or diphtheria, while other children of the same family continued to go to school and thus jeopardized the life of every person who breathed the same air with them in the school room. Although it is a fact that there exists a law to the effect that all communicable diseases shall be reported to the Bureau of Statistics for Contagious Diseases, and that immediately thereon measures shall be adopted by the Board of Health to prevent the spread of the disease, and that this law is actively and beneficially enforced, everyone knows that at least one-third to one-half of all the cases of these three diseases—measles, scarlatina, and diphtheria—are allowed to run their course without the aid or attention of a physician. In many other cases the services of a physician are not sought until the patient is *in extremis*, and even then the child is often taken to a dispensary.

Since the serum treatment of diphtheria has become so universal, and since cultures for the early diagnosis of the disease have become the rule, the fact that many cases of genuine diphtheria formerly passed as tonsillitis, pharyngitis, catarrhal sore throat, and the like, cannot be gainsaid. It is to these and similar cases that we owe the spread of so much diphtheria and scarlatina by the public schools, and it is these cases particularly that the corps of physicians which it is proposed to appoint would combat, and in a measure prevent. We are sure that the immediate result of the expenditure of this insignificant sum of money will be to materially lower the death-rate.

THE FATE OF CHARLATANS IN GERMANY.

THERE are times and places in which charlatanism is not all profit. The writer of an article which appeared in the *Journal de Médicine* of Paris, December 20, 1896, laments the fact that if a charlatan is brought to trial in France he is either acquitted or escapes with a fine of 15 francs ($3).

It is somewhat different in Germany. A certain Volbeding of Dusseldorff, who styled himself a homeopathist, by advertising in more than six hundred newspapers in Germany and elsewhere, worked up a business estimated to be worth $40,000 a year. He treated patients by correspondence, and employed a small army of clerks, without medical knowledge, to answer the several hundred letters he daily received; and they, in his absence, prescribed the treatment. The medicines he used were few and simple, and were prepared in his laboratory by other clerks who knew nothing of pharmacy. He "cured" nearly everything and regulated his charges according to the social status of his victims. In the front of his establishment he kept a neat little drug-store to conceal the business which was done in the rear. Moreover, he himself was a regularly graduated physician. In spite of all these precautions he was arrested and sentenced to four years and a month imprisonment, to five years' loss of civil rights, and to pay $1500 fine. Pending his trial he deposited $50,000 as bail, but, unfortunately for him, he did not obtain even temporary liberty, as the tax collector accused him of having committed fraud in the avoidance of taxes upon his revenue. The officer therefore confiscated the whole sum, and Mr. Volbeding remained in jail.

ECHOES AND NEWS.

Roentgen-ray Experiments.—The Prussian Government is reported to have appropriated $12,000 for Röntgen-ray experiments during the current year.

Memorial of Baron Hirsch.—The widow of Baron Hirsch has presented the Pasteur Institute in Paris with 2,000,000 francs as a memorial of her late husband.

A National Laboratory.—Great Britain is now seriously considering the advisability of establishing a National Laboratory of Natural Sciences, in which all her scientific associations will take an interest.

Epidemic Diseases in Paris.—During the period between 1877 and 1881, the death-rate in Paris from preventable epidemic diseases was one in every ten. This was reduced during the years 1892–1896 to one in eighteen.

Following the New York Health Board.—Health Commissioner Starkloff will, at the next meeting of the St. Louis Board of Health, recommend that pulmonary tuberculosis be declared infectious, as has been done in New York City.

Temples of Esculapius.—Recent excavations at Epidaurus and Athens have opened to modern eyes the temples of Esculapius, and the ruins are found to bear much valuable evidence regarding the methods of ancient medicine.

Concert for the Post-Graduate Hospital.—A successful concert was given recently by Mr. Seidl and his Metropolitan Orchestra at Carnegie Hall for the benefit of the New York Post-Graduate Hospital. Mme. Gadski and Mr. Emil Fischer rendered the special numbers of the program.

Lung Troubles in Chicago.—Since the first day of the present month, pneumonia and other pulmonary troubles have been increasing in Chicago, and it is feared that pneumonia may become epidemic. In December, 1896, there were 147 deaths due to that disease. Thus far in January it has claimed 167 victims.

Lord Lister.—Sir Joseph Lister has communicated his intention of retaining the name Lister in the title he will assume when elevated to the peerage. It is a source of gratification to his medical friends and admirers to learn that he will not abandon the name he has rendered renowned and so universally revered.

A Medical Strike.—The physicians attached to the night service in a certain densely inhabited quarter of Paris have all resigned. Applications customarily made to the police for medical relief are now refused in most instances. The difference has arisen concerning the remuneration. To one at this distance the sum in question is a paltry one, but a principle of no small importance may be involved.

Famine in Rhodesia.—Reports have been received from Cape Town that famine exists in Rhodesia. Thousands of emaciated native women besiege the native office at Buluwayo, clamoring for food. The natives are flocking to Buluwayo and are exhuming the carcasses of cattle which died from rinderpest. They devour these, and, as a consequence, a terrible mortality prevails among them.

Changes in the Medical Staff of the Woman's Hospital of New York.—The Medical Board of this hospital has decided that it is for the best interests of the institution that the Assistant Staff should be reduced in number. Accordingly the edict has gone forth that each visiting surgeon, instead of having two assistants, shall hereafter have but one, and five members of the Assistant Staff have been dismissed.

Tri-State Medical Society of Iowa, Illinois, and Missouri.—The fifth annual meeting of this Society will occur in St. Louis, April 6, 7, and 8, 1897. Dr. Joseph Price of Philadelphia will hold the Surgical Clinic, Dr. James T. Whittaker of Cincinnati the Medical Clinic, and Dr. Dudley Reynolds the Ophthalmic Clinic. Dr. G. Frank Lydston of Chicago will entertain the members with an original story during one of the evening sessions.

Air and Exercise for Consumptives.—At the recent discussion on phthisis before the New York Academy of Medicine, Dr. Trudeau asserted that exercise was not so desirable in the case of a phthisical patient as was generally supposed, the slightest excess, indeed, being injurious and working with surprising rapidity against the ability of the sufferer to resist the disease. He insisted, however, on the greatest amount of exposure to the outside air, even in inclement weather and at low temperatures.

The Albany Medical College Alumni Association.—The second annual banquet of this organization was held at the Hotel Savoy in New York, January 21, 1897. Dr. Wm. H. Thomson, the president of the Society, welcomed the guests in a most interesting and delightful way. Among other enjoyable features of the evening was the amusing and graphic description by Dr. Kimball (now detailed at Governor's Island) of his medical and surgical experiences upon the western frontiers, especially among the Indians.

Appropriation to Protect New York Against the Bubonic Plague.—Health Officer Doty of the Port of New York made a personal appeal to the legislature in Albany last week for an appropriation of five or six thousand dollars to be used in extending his present disinfecting plants. The existing facilities are quite sufficient to care for all suspicious mail, but within the next few weeks it may become necessary to deal with infected vessels. To prepare for this is part of an efficient service such as Dr. Doty is sparing no pains to render.

Pursuing Quack Doctors.—The New York County Medical Society is after the unregistered doctors and quacks who are practising medicine without a license. Since the law providing for the criminal prosecution of the quacks was reënacted in April, 1895, the Society has caused the arrest of eighty-three persons for practising illegally in the county, and has obtained convictions in fifty-one cases. These persons have paid $3,690 in fines, and in addition a number of them have been sent to jail. The legal department of the society has a large number of cases still pending.

The Board of Health Sustained.—In an action brought by the New York Board of Health in the Supreme Court to compel the removal of certain rear tenements in Mott street, the referee filed his report this week. In this he sustained the action of the Board of Health in every particular. As this case was generally accepted as a test of the validity of the Act of 1895, upon it will hinge the destruction of more than fifty of these vile pest-holes of moral and physical degradation. The final approval of the judge it is hoped will forever set a seal upon the existence of rear tenements in New York City.

Spitting in Public Conveyances.—Placards carrying the full text of an act of the New York Board of Health against expectoration in public places, including street and elevated cars, have been displayed in conspicuous positions in the same for almost a year, but still the vile, disgusting, and dangerous practice persists with little abatement. The police authorities are now being directed to look to its enforcement. The conductors and station masters have apparently come to regard it as a dead letter, and it is quite as important that their minds should be relieved of this false impression as that the public violators should be brought to justice.

A Nun Doctor.—Many Roman Catholic Sisters are more or less skilled in the practice of medicine, and the nursing of the sick is, very appropriately, among their most frequent benevolent vocations; but it is by no means usual to find one who has fulfilled the legal requirements necessary to allow her to write M.D. after her name. Sister Raphael, an inmate of a convent in Kalamazoo, Mich., is an exception. She graduated from one of the best Philadelphia colleges, and afterward joined the religious order of the Sisters of St. Joseph. In a well-appointed office in the convent she attends to a regular office practice, both medical and surgical, and is highly esteemed by her professional neighbors.

Serum Treatment of the Bubonic Plague.—Dr. Yersin has so conclusively demonstrated the efficacy of the serum treatment of this infectious disease in India that he has begun the manufacture of the serum on a large scale. He has inoculated 100 horses, in which he is developing the antitoxin as rapidly as possible for use not only as a specific against the disease, but also as a prophylactic. At present he has at his disposal the serum from a single horse. With this he has inoculated twenty-seven patients sick with the plague, of whom twenty-three have recovered. When his present plans are perfected, he will have sufficient serum to inoculate 18,000 persons every month.

Disinfected the Mail.—Nine sacks of mail from India came into New York Harbor last week and were taken off the steamer at Quarantine for disinfection. It is the first batch received since the rule went into effect for special precautions, in view of the bubonic plague that is devastating Bombay and the far East. Dry heat is the main reliance for killing any lurking microbes. Chambers have been provided on the new quarantine boat, where treatment can be given by heat, steam, formalin, or bichlorid of mercury. Formalin is a saturated solution of formaldehyde, a deadly gas derived from methyl-alcohol. When the solution is poured out, the gas is set free and seems to penetrate everything. A heat of 230° F., however, is considered absolutely sufficient to kill any germ.

Localizing the Seat of Memory in the Brain.—Professor Edniger of Frankfort-on-Main is collecting evidence to determine the question: Do fish possess the faculty of memory? The Professor maintains that it is accepted that fish do possess a certain degree of memory; that they recognize persons, know which places to frequent and which to avoid, according to the experience they have gained; and that having once been caught by a hook, they recognize it when they see one again. It has generally been held that the seat of memory is in the gray matter of the brain. Fish have no gray matter whatever. If, therefore, it can be proved that they collect their experiences and utilize them afterward, it will throw doubt upon the exclusive claim of gray matter to the seat of memory.

CORRESPONDENCE.

OUR PHILADELPHIA LETTER.

[From our Special Correspondent.]

ELECTION OF OFFICERS OF THE PHILADELPHIA COUNTY MEDICAL SOCIETY—MEETING OF THE SECTION OF OPHTHALMOLOGY OF THE COLLEGE OF PHYSICIANS—MEETING OF THE MUTUAL AID ASSOCIATION OF THE COUNTY MEDICAL SOCIETY—ON THE ALERT TO AVOID THE PLAGUE—VISIT OF PROMINENT PENNSYLVANIANS TO INSPECT THE WORKINGS OF THE NEW YORK HOSPITAL FOR THE CRIMINAL INSANE—ANNEX TO THE MUNICIPAL HOSPITAL—DR. SPEAR APPOINTED SURGEON TO THE SCHOOLSHIP "SARATOGA"—MEETING OF THE GYNECOLOGICAL SECTION OF THE COLLEGE OF PHYSICIANS.

January 24, 1897.

AT a business meeting of the Philadelphia County Medical Society, held January 20th, the following officers were elected: President, Dr. James Tyson; first vice-president, Dr. Edward Jackson; second vice-president, Dr. S. Solis-Cohen; Secretary, Dr. John Lindsay; assistant secretary, Dr. Edward R. Kirby; treasurer, Dr. Collier L. Bower; censor, Dr. W. Joseph Hearn. Delegates to the American Medical Association and to the State Medical Society were also chosen.

At a meeting of the Section of Ophthalmology of the College of Physicians, on January 19th, Dr. Clarence A. Veasey, by invitation, read a paper on "Binasal Hemianopsia." Dr. G. Oram Ring reported a case of foreign body in the vitreous diagnosticated by aid of the Röntgen ray. Some instances of magnet extraction of steel from the vitreous were related by Dr. Edward Jackson. Dr. F. M. Perkins exhibited a case of unilateral congenital microöphthalmos. A paper treating of traumatic ectropion uveæ and also of syphilitic tarsitis was contributed by Dr. George E. de Schweinitz. A patient with cilia in the anterior chamber was presented by Dr. George C. Harlan. Dr. Charles A. Oliver read a paper on the primary effects of an operation for cicatricial ectropion, exhibiting two patients, and a third illustrating rupture of the retina in retinal detachment.

A special meeting of the Mutual Aid Association of the Philadelphia County Medical Society was held on the evening of January 23d, to consider methods of increasing the permanent fund and adding to the membership of the organization. The Association consists of members of the Philadelphia County Medical Society, and its purpose is to give pecuniary assistance to the widows and children of physicians who have left no estate. It was founded in 1878, largely through the efforts of the late Professor Henry H. Smith, of the University of Pennsylvania.

At the weekly meeting of the Board of Health, held Wednesday, January 20th, Dr. William H. Ford was appointed a committee of one to confer with the secretary of the State Board of Health and the quarantine physician on the subject of the bubonic plague, with a view of preventing the possibility of its entry into this port.

The New York Hospital for the Criminal Insane at Matteawan was visited yesterday by Judge Gordon and a delegation of about thirty prominent Pennsylvanians. Among the number were Dr. Thomas G. Morton, former member of the State Lunacy Commission; Dr. William S. Janney; Dr. Francis X. Dercum; Dr. John C. Chapin, superintendent of the Pennsylvania Hospital for the Insane; Dr. D. E. Hughes, of the Insane Department of the Philadelphia Hospital; Mayor Warwick; Judge Arnold; Henry M. Deckert, president of the Wernersville Insane Hospital; Albert R. Harris, Eugene Raymond, and William F. Santly, of the House of Representatives; and General J. P. S. Gobin, Senator from Lebanon County. This visit of inspection is the result of the investigation recently ordered by Judge Gordon into the mental condition of certain convicts confined in the Eastern Penitentiary, this city, and it is to be hoped that it will ultimately result in the establishment in this state of a hospital fitted for the accommodation and treatment of the criminal insane.

An annex to the diphtheria pavilion and an administration building for the Municipal Hospital of Philadelphia have just been completed, and were thrown open for inspection during the past week. The new pavilion leaves nothing to be desired from the standpoint of ventilation, the air being continually changed by a system of electric fans.

Dr. Raymond Spear of Norristown, Pa., has recently been appointed surgeon to the schoolship "Saratoga" during her coming cruise. This position is generally filled by an officer of the U. S. Naval Medical Corps. Because of the number of men-of-war going into commission, none of the regular corps was available for the "Saratoga," and a civilian was of necessity detailed to the post.

At a meeting of the Section of Gynecology of the College of Physicians, held January 21st, Dr. Charles P. Noble read a paper entitled "A New Method of Suturing the Abdominal Wound in Celiotomy." Dr. Richard C. Norris read a paper on "The Necessity for an Early Inspection of the Vagina in Puerperal Sepsis." The discussion of Dr. Norris' paper agreed in the main with his views, differing only in matters of detail as to treatment, etc. Dr. E. E. Montgomery suggested the use of streptococcus antitoxin serum when infection of this type was suspected.

TRANSACTIONS OF FOREIGN SOCIETIES.

Paris.

NATURE OF THE CONTAGION AND THE ORIGIN OF INFECTIOUS DISEASES—THE ROENTGEN-RAY IN THE DIAGNOSIS OF PULMONARY CONSOLIDATION—ACQUIRED AND HEREDITARY SYPHILIS IN THE SAME INDIVIDUAL.

KELSCH read a paper on *contagion and the origin of infectious diseases* before the Academy of Medicine, December 22, 1896. The propagation of infectious diseases capable of becoming epidemic is attributed to direct contagion, each attack presupposing a similar attack in another person. Though this is true of certain diseases (more particularly of eruptive fevers), it does not hold good for the most important group of epidemic infections.

These not only develop through contagion, but also in many cases where they do not previously exist. This statement is true of typhoid fever, cholera, diphtheria, and epidemic influenza. There is no doubt that typhoid fever may break out suddenly in places where it had not existed within human memory; where no typhoid fever patients had arrived from other places, and where no influence from other typhoidgenic foci in the neighborhood could make itself felt. These facts prove that typhoid fever may arise, not indeed spontaneously, but from agents, either inside or outside of our organism, which are ordinarily inoffensive.

The history of cholera is likewise full of sporadic and epidemic cases in which the ubiquity and simultaneousness of the attacks defy any attempts to connect them, while it is evident to any unprejudiced observer that they have originated on the spot. This idea has recently received bacteriologic confirmation by the proof that there almost invariably exist in sewage and other waters vibrios representing all the characteristics of the cholera vibrios, but without their virulence. Experiments have shown that they may acquire virulent properties by changes in the chemic and biologic composition of the medium in which they live. In explaining the epidemics of influenza it is necessary to introduce these two etiologic elements, namely, contagion and autochthonous development; for we frequently meet with local epidemics with individual cases occurring simultaneously in widely separated places and under conditions which argue against the probability of the transport of a morbid germ by human beings or by atmospheric currents. A similar statement holds true of diphtheria. And, indeed, there is nothing mysterious about these facts since we know that Loeffler's bacillus is normally present in the mouth of many persons, as is also the pneumococcus and streptococcus, and that it is capable of acquiring an unusual virulence under the influence of undetermined causes. Therefore, while infectious diseases are transmissible by contagion, like virulent diseases properly so-called, they are not exclusively contagious like the latter. Hence the name infecto-contagious, by which they were formerly known.

Another interesting feature of infectious diseases is brought out by the study of their course during a number of years. A virulent period of smallpox recurs on an average every eight or ten years; of measles every three or six years; and of scarlet fever at longer and more irregular intervals. It is clearly indicated that the contagious agent of these diseases undergoes in the course of time unceasing variations, its ascerbation and attentuation alternating with greater or less regularity. Proofs of this theory are also not lacking in the history of those parasitic diseases which are capable of becoming epidemic. Alopecia areata has been endemic among the firemen in Paris for nearly ten years. During this time there have been two epidemic periods, one in 1888 and the other in 1893. The most careful investigation failed to reveal the cause of this sudden extension of the disease. The only conceivable explanation is that the infected agent in some unknown way acquired an unusual energy. The search for various cosmic, telluric, hygienic, and other influences, which cause germs, ordinarily harmless, to take on virulent functions is of as great importance as the search for the origin of the contagion itself.

BOUCHARD recently called the attention of the Academy of Sciences to the arrest of the Röntgen ray by pleural effusions. At the session held December 14, 1896, he reported that even slight condensation of the pulmonary tissue at the apex of the lung will cast a dark shadow. By examination of a number of tuberculous patients with the aid of the fluorescent screen, it was determined that the pulmonary lesions threw shadows which corresponded exactly with the area of consolidation as revealed by other means of physical examination. In two cases, light spots within the dark area revealed cavities, the existence of which was proved by auscultation. In other cases in which cavities were made out by auscultation, no light spots were seen in the shadow.

In a communication on the *regulation of the intrabronchial pressure and narcosis in artificial respiration by insufflation* made to the Biological Society, December 19, 1896, **TUFFIER** and **HALLION** explained the advantages of their apparatus for insufflation. In order to vary the narcosis, it is only necessary to change the rhythm of the insufflation, or to cause expiration to go on through a tube plunged in water to a greater or lesser depth. The resistance to the respiration varies with the depth of the tube under water, and the intrabronchial pressure and the volume of the lungs can thus be regulated at will. On the other hand, by inserting into the adductor tube a branch tube which passes through a a bottle containing chloroform or ether, the current of air for insufflation may be made to pass in any desired proportion through this bottle, where it becomes charged with narcotic vapor.

MARIANI invariably found that inhalations of oxygen brought about important changes in the urine, namely, increase in the amount of urea and nitrogen, and diminution in the amount of the toxicity. On the other hand, he observed a marked alkalinity of the blood. He therefore concluded that inhalations of oxygen may be advantageously resorted to in all infections associated with disturbances of the organic exchanges.

LE PILEUR called the attention of the Society of Dermatology and Syphilography on December 10, 1896, to *acquired syphilis in a patient suffering from hereditary syphilis.* His mother, for some months previous to his birth, had undergone treatment with mercury, and was delivered at term. The father was an alcoholic, and had contracted syphilis six years before the birth of this child. The child's physical and intellectual development was imperfect. The skull was remarkably small and the face dull. The roof of the mouth was extremely narrow and the teeth were small, stubby, and covered with striæ and erosions. When nineteen years of age, he contracted syphilis during coitus, and two months later presented a hard chancre in the balanopreputial furrow, and, in addition, roseola, sore throat, headache, etc.,—in short, all the usual symptoms of acquired syphilis. It was evident, therefore, that a subject of hereditary syphilis might acquire syphilis, or else the above trophic disturbances must be considered as belonging to the lesions described by Fournier as parasyphilitic.

Vienna.

TWO CASES OF THRUSH OF THE BLADDER—A TUMOR OF THE STOMACH WHICH DEVELOPED UNDER THE EYE OF THE OPERATOR—THERAPEUTIC VALUE OF CATHETERIZATION OF THE URETERS—BEST TREATMENT OF CHRONIC CONSTIPATION.

At the session of the Society of Physicians held December 11, 1896, FRISCH presented a patient with *thrush of the bladder.* The attack was sudden, without known cause, and was accompanied by painful micturition. The use of a catheter showed the presence of air in the bladder, and the last few drops of urine that were drawn off were mixed with bubbles of air. The urine contained traces of albumin, four per cent. of sugar, and a great number of small white kernels, which the microscope showed to be mycelia. The urinary sediment also contained yeast cells.

BRIK mentioned a very similar case observed by him in which the etiology was especially interesting. The patient, an officer of past middle life, was diabetic and had had several attacks of cystitis and pneumoturia. In a recent attack, marked by a great sensitiveness above the symphysis, the catheter was completely stopped up by a white membrane in which numerous bacteria, threads of mycelium, and yeast fungi, were demonstrable. The patient, who suffered with thrush in the throat, and who for convenience always carried his catheter in his pocket, had the habit of moistening the instrument in his mouth before inserting it into the bladder. The symptoms of thrush in the bladder improved after injections of nitrate of silver.

SCHNITZLER had a patient, aged thirty-five, whose mother died from cancer of the stomach, and whose sister also died from some gastric trouble. For eleven years this patient had suffered from oft-recurring severe gastric pain, and said that she had vomited great quantities of blood. She was kept in bed for a time on a milk diet, and did not vomit at all. Six months later she returned to the hospital with the statement that during her absence she had vomited blood many times and had suffered almost constant pain. Abdominal palpation was negative. Two days later, however, a tumor was plainly made out in the region of the stomach. An exploratory laparotomy was performed, and the stomach found to be apparently normal. Suddenly there developed a tumor of the pyloric region about 7 cm. long and 5 cm. wide. It was very hard and obstructed the lumen of the stomach. This tumor, which was due to muscular contraction, was either purely hysterical or was of a reflex character, caused by the presence of an ulcer of the stomach. An incision was made through it longitudinally, but neither a fresh ulcer nor a cicatrix was found; in fact, nothing abnormal was seen. The incision was sutured transversely in order to prevent the same muscle fibers from growing together. Since the operation there have been no attacks of pain. Although this is the only case in which such a spasm has been directly observed, cases with similar histories have been operated upon but nothing found.

KOLISCHER discussed the *therapeutic value of catheterization of the ureters.* This procedure may be of therapeutic advantage in three ways; first, by pushing back into the pelvis of the kidney a stone which has become wedged in the ureter, thereby preventing the escape of urine; second, by breaking a soft calculus into small pieces; and third, by assisting the passage of the stone into the bladder. This actually happened in one of Kolischer's cases in which he injected 3 grams of liquid vaseline through a catheter inserted into the ureter to the distance of 3 cm. The calculus was passed into the bladder in three-quarters of an hour.

BUMM discussed the *best treatment of chronic constipation* at the session of the Medical Club, held December 16, 1896. Massage, electricity, gymnastics, and hydrotherapy, were all favorably mentioned. Purgatives are seldom of value. It is important to know in what part of the intestine the fecal masses accumulate. He had noticed in gynecologic examinations that the rectum was often filled with feces, although the patient had asserted that her bowels moved regularly; while women in whom the rectum was empty complained of constipation. In such cases the seat of fecal accumulation is not in the lowest part of the large intestine, but is frequently in the region of the splenic flexure, a point which should be remembered in the treatment. Moreover, massage is to be looked upon not as a mechanical means of pushing along the feces, but as a passive gymnastic exercise of the intestinal wall. Massage also increases the flow of bile which in turn favors the evacuation of the intestine.

SOCIETY PROCEEDINGS.

NINETY-FIRST ANNUAL MEETING OF THE MEDICAL SOCIETY OF THE STATE OF NEW YORK.

Held in Albany, January 26, 27, and 28, 1897.

[From our Special Correspondent.]

JAMES D. SPENCER, M.D., of Watertown, President.

FIRST DAY—TUESDAY, JANUARY 26TH.

THE meeting was called to order by the President, and prayer was offered by the Rev. Dr. Selden of Albany.

The

PRESIDENT'S INAUGURAL ADDRESS

was then delivered by JAMES D. SPENCER, M.D. He said that much good work had been done by the State Board of Health, but their work was largely a labor of love, and required the expenditure of much time. They should have at their disposal the necessary funds for prosecuting the very important work of thoroughly inspecting cattle, and detecting those which are diseased. This inspection should be carried out in a scientific manner, and demands the services of a skilled bacteriologist. The offensive trades should also be placed within the jurisdiction of the State Board of Health.

A movement was on foot, the speaker said, looking to the organization of a body to be known as the "National Confederation of Committees on Legislation of State Medical Societies." It was to be so constituted as to be an amplification of the committees on legislation of the various State Societies throughout the Union. It was recommended that this Society should appoint a committee of five or ten members to consider this matter, and, if deemed advisable, to represent the Society in this proposed national organization.

The subject of the work of the Board of Regents was next considered. It was stated that New York State had nearly seventeen per cent. of all the medical students of the United States. Of the 2273 candidates who had taken the licensing examinations, over twenty-two per cent. had been rejected. Of the 733 candidates last year, 181 were unsuccessful.

The announcement was made that the Society had been invited to send a delegation on May 8, 1897, to the centennial celebration of the Westchester County Medical Society—the oldest medical society in the State.

STATE MEDICAL EXAMINATIONS.

M. J. Lewi, M.D., presented a report on this subject. He said that 23.7 per cent. of the candidates had been rejected at the examinations. Of those coming from the medical schools of New York State 86.2 per cent. received licenses, whereas of those graduated from schools outside of the State only 74.5 per cent. passed the examinations. An applicant must receive 525 points out of a possible 700 to receive a license to practice medicine. A neighboring State has made the claim of a higher standard, because their candidates were required to obtain 675 points, but a careful consideration of their method of rating would show that 675 points were required out of a possible 900—exactly the same standard as prevails in our own State. Since the enactment of the laws which established this Board in our State 1893 licenses have been granted. In this same period 2832 persons have applied for licenses to practice medicine. Of this number 29.2 per cent. were found incompetent and deficient.

After adopting this report the State Medical Society passed a resolution requesting that the Legislature should not interfere with the law as it now stands, unless requested to do so by this Society.

REPORT OF COMMITTEE ON LEGISLATION.

A. Walter Suiter, M. D., of Herkimer, the chairman, presented the report. He stated that the committee had not succeeded in securing the repeal of the law requiring public school instruction in the effects of alcohol and narcotics, but had secured a favorable modification of the same.

It was expected that a bill would be introduced shortly requiring the licensing of midwives by the Regents of the University, after proper examination and on the same grounds as licenses were granted for the practice of medicine. The proposed measure would contain one provision, which had unfortunately been omitted from the medical practice law, *viz.*, the power to revoke a license for cause.

It should be noted that the Stanchfield bill, which proposed to restore the matriculation examinations to the hands of the faculties of the medical colleges, had been vigorously and successfully opposed, not only by the medical societies, but by the faculties of all the colleges in the State, *save one.*

The bill to incorporate the "Optical Society" was defeated. Had it passed, it would have allowed 4000 persons in the State to become, in a certain sense, licensed practitioners.

So much objection had been raised to the method provided for in the bill abolishing the coroner's office for appointing the medical examiners, that this bill had been defeated. The committee hoped to advocate another similar bill before the present legislature.

REPORT OF COMMITTEE ON HYGIENE.

Henry R. Hopkins, M.D., of Buffalo, the chairman, presented the report. He said that as the mortality for the last year reported was 38,000 from contagious, infectious, and communicable diseases, there was abundant reason for giving much attention to the subject of hygiene. The committee recommended that the society ask the various county organizations to establish local societies to consider especially matters relating to the public health.

The report of the committee was accepted, and the last recommendation especially commended.

VIVISECTION.

On motion of Dr. Vanderveer of Albany the Society instructed the secretary to notify Senators Hill and Murphy that it had adopted a resolution condemning Senate bill No. 1552, entitled "An act for the further prevention of cruelty to animals in the District of Columbia."

On motion of Dr. W. O. Stillman of Albany the Society also appointed a committee to confer with the Humane Society on this matter.

PRELIMINARY MEDICAL EDUCATION.

Daniel Lewis, M.D., of New York, offered the following resolution: That the Committee on Legislation be requested to prepare and present to the Legislature an amendment to the present medical law, allowing medical students, graduates of literary colleges, credit for the last year of study in such literary colleges.

Dr. D. B. St. John Roosa, of New York, said that in this country our zeal had led us to exceed even the requirements of Germany. According to present legislation, a man who desired to receive a liberal education in addition to his medical course and term in a hospital, could not begin the practice of medicine before the age of thirty years. In Germany the study of medicine was begun at about the age of our sophomores. The resolution was adopted.

Scientific Session.

Lucien Howe, M.D., of Buffalo, presented a *résumé* of a carefully prepared paper on

A GEOGRAPHY AND ARITHMETIC LESSON ON BLINDNESS IN NEW YORK STATE.

He said that his statistics would show that it is possible to lessen the blindness in this State by one-tenth, and reduce the cost to the State of caring for the blind $50,000 annually. A recent examination of over 3000 children in the two asylums of this state showed that purulent ophthalmia was responsible for twenty-one per cent. of the cases of blindness in these little ones, and for a little over ten per cent. in those of all ages. This large amount of blindness is attributable to: (1) The negligence of the obstetrician in omitting Credé's method for preventing ophthalmia; (2) the negligence of the attendants in obtaining prompt relief; and (3) to the inability of the oculist, in about five per cent. of the cases, to prevent the destruction of the eye in purulent ophthalmia. The author indorsed the conclusion of Cohn of Breslau, based on a tabulation of 3000 cases—*i.e.*, that ophthalmia neonatorum can be, and must be, wiped out from every civilized country.

Matthias L. Foster, M.D., of New York, presented a paper on

THE FITTING OF GLASSES.

He advised; (1) To test the vision of each eye at twenty feet; (2) to examine the eyes with the ophthalmoscope; (3) determine the amount of corneal astigmatism; (4) correct the principal refractive error; (5) determine the range of accommodation and add such spherical lenses as may be necessary to correct any presbyopia; and (6) ascertain any muscular error, and, after repeated examinations only, determine whether it is necessary to correct this error.

Dr. St. John Roosa said that an experience of half an hour with the ordinary tests should make the general practitioner an expert in testing vision.

Charles W. Cox, M.D., of Brooklyn, read a paper on

A CONTRIBUTION TO THE STUDY OF COUGH DUE TO IRRITATION OF THE UPPER RESPIRATORY TRACT.

He said that the two regions most provocative of nasal cough were the posterior ends of the inferior turbinated bodies and the posterior end of the septum. Cough, particularly "morning cough," is often due to irritation in the naso-pharynx from adenoids, or the accumulation of viscid, tenacious mucus. The glazed mucous membrane found in atrophic rhinitis may also excite cough, as may also, in exceptional cases, papillomata of the soft palate. The important bearing of these considerations on the therapeutics of cough is evident. A constant and useless cough is not entirely devoid of danger.

Dr. John O. Roe of Rochester said that when there was no expectoration, cough must be looked upon as the result of some irritation in the upper respiratory tract. One of the most prolific sources of cough is a glandular hypertrophy or an aneurismal varix at the base of the tongue.

James K. Crook, M.D., of New York read a paper on

PRACTICAL CONCLUSIONS BASED ON 500 CASES OF CARDIAC DISEASE. THE COMPARATIVE PROGNOSIS OF THE VALVULAR LESIONS.

Out of a total number of 5817 cases on the dispensary record 3334 were males and 2483 females, of all ages over fifteen years. There were 277 cases of functional, and 226 of organic heart disease; 60 of mitral regurgitation; 35 of mitral stenosis; 7 of aortic regurgitation; 36 of aortic stenosis; 6 of tricuspid regurgitation; 1 of pulmonary stenosis: 19 of double aortic lesions, and 12 of double mitral lesions. Of the males, 149, or 4.45 per cent., suffered from functional, and 137, or 9.01 per cent., from organic heart disease. Of the females, 128, or 5.15 per cent., had functional, and 86, or 3.46 per cent., had organic cardiac disease. In the males, the three principal causes of functional disorders of the heart were: (1) disturbance of digestion; (2) excessive use of tobacco; and (3) excessive use of alcohol. Among the females, the functional disorders were mainly due to indigestion, anemia, and chlorosis; in only a very small proportion were they the result of excessive tea-drinking.

The hemic murmurs, Dr. Crook said, were almost invariably systolic. They were heard over the aortic and pulmonary areas, were usually transmitted to the great arteries of the neck, and, in the majority of cases, were accompanied by a venous hum. These blood murmurs are rarely audible below the third rib. In his experience the "water-hammer" pulse had been present in every case of aortic regurgitation. This sign seemed to be even more constant than the murmur itself. While mitral regurgitation is the most frequent lesion, it is also the most tractable and hopeful.

Richard Van Santvoord, M.D., of New York called attention to the fact that we had in the sphygmograph a ready means of determining the amount of regurgitation and of obstruction at the aortic orifice. Referring to the "water-hammer pulse," he said that the failure of the dicrotic impulse might be due as much to the lack of elasticity in the aorta as to the amount of regurgitation at the valvular orifices.

Eli H. Long, M.D., of Buffalo said that to differentiate between diastolic and systolic murmurs one had only to make intermittent pressure on the radial pulse and note whether or not the murmur is synchronous with the radial pulsation.

Woods Hutchinson, M.D., of Buffalo read a paper on

SOME DISEASES OF THE ALIMENTARY CANAL, IN THE LIGHT OF ITS DEVELOPMENT AND ANCESTRY,

in an effort, as he said, to apply the comparative method of study to pathology, following out the lines of the address delivered before this Society last year by Dr. Roswell Park. He said that the most primitive stomach is the depression found in the ameba. In this organism, if one stomach were unsatisfactory, another depression could be made to serve the purpose. The first permanent stomach in the scale of evolution is to be found in the protozoa. He said that one of the best morphological definitions of man is "a stomach and its appendages." An infant stomach is practically in the "fish stage;" in other words, the human infant is essentially carnivorous in its tastes. If sacculation and enlargement of the stomach go beyond a certain point, the proper motility of the organ is lost and serious pathological conditions result. The greater the *normal* distention of the stomach in a given class of animals, the greater the pathological significance of any undue distention. This is well illustrated in the herbivora.

EMIL MAYER, M.D., of New York presented a paper on

SOME UNUSUAL CAUSES OF COUGH,

and drew the following conclusions: Cough is reflex in origin (1) when spasmodic and almost constant, without expectoration and elevation of temperature; (2) when the physical signs of pulmonary disease are absent; (3) when it persistently resists all medication; (4) when the general health is comparatively undisturbed, and (5) when, upon the removal of the cause, the cough promptly ceases.

ELI H. LONG, M.D., of Buffalo, in a paper entitled

DOES THE U. S. PHARMACOPEIA KEEP PACE?

referred to the fact that the New York State Medical Society, at the instance of the New York County Society, had issued the original call for a meeting, looking toward the adoption of a National Pharmacopeia. While this work originated with the medical profession, to-day the pharmacal institutions and societies predominate in the work of revision. It would seem better to have an equal representation of the two professions. He suggested that in the next pharmacopeia, a section should be devoted to furnishing reliable information concerning new drugs of tried value, and that each year a supplement to this should be issued. If it were thought best to include the matter of dosage, it would be least objectionable to do this in the index, where the dosage given would not be looked upon as giving an authoritative standard.

AFTERNOON SESSION, JANUARY 26.

CLARENCE C. RICE, M.D., of New York, read a paper on

THE EFFECT OF CIGARETTE SMOKING ON THE RESPIRATORY MUCOUS MEMBRANE.

He stated that while most writers asserted that cigarette smoking produces only a moderate degree of congestion of the mucous membrane, his experience indicated that it was responsible for the production of marked atrophic nasal catarrh, with a glazed pharyngeal mucous membrane.

The forced and oft-repeated inspirations, the rapid evaporation from the mucous surface, and the irritation produced by the smoke, are certainly sufficient to give rise to inflammation.

CHARLES E. LOCKWOOD, M.D., of New York, presented

A CONTRIBUTION TO THE STUDY OF AMEBIC DYSENTERY.

He reported a case of amebic dysentery that had recently come under his observation, and from a study of this, made the following deductions: (1) It is important to differentiate this form of dysentery from the others; (2) the feces should be examined microscopically in all cases of obstinate diarrhea characterized by remissions and exacerbations, with a notable tendency to chronicity and anemia, if accompanied by offensive, brownish-yellow, liquid stools, and colicky pains; (3) in these cases, rectal douches of bisulphate of quinin, 1–5000 or 1–1500, are markedly efficient; (4) it is important to make an early diagnosis, before the parasite has penetrated the submucous tissues, for, if this should occur, it is likely to lead to abscess of the liver; (5) these cases are liable to relapse, even after considerable time; (6) it is not improbable that there is a kinship between the ameba and the organism of intermittent fever; and (7) there is a possibility that acid solutions are beneficial in this disease, as they are inimical to the amebæ.

JOSEPH EASTMAN, M.D., of Indianapolis, by invitation, presented a paper on

FANCIES AND FACTS IN OUR WORK.

He said that many a life had been sacrificed by the fancied chemical sterilization of the hands and instruments, to the neglect of mechanical sterilization with soft soap and the nail-brush. Speaking of pelvic inflammation, he said that it was wrong to resort to the vaginal route, when the abdominal route was equally available, for it involved the destruction of the pelvic floor and vaginal vault. For cancer, vaginal hysterectomy was especially valuable, if done by an expert. All physicians should bear in mind that at the menopause, unless a discharge is absolutely *symptomless*, it calls for a searching examination.

Regarding appendicitis, or cases of suspected intestinal obstruction, the speaker said that these cases should be treated either medically or surgically, and not by a "fatal compromise" of the two. We should no more countenance the use of purgatives in these cases than in strangulated hernia.

DR. A. PALMER DUDLEY expressed the opinion that the chief cause of the mortality in suppurative appendicitis is the enthusiasm of the surgeon in his efforts to remove the appendix in all cases.

DR. GEORGE R. FOWLER of Brooklyn protested against the plan of invaginating the appendix during an abdominal operation, done for other lesions, as he had known it to result in gangrene and fatal sepsis.

DR. EASTMAN replied that during the past few years he had invaginated the appendix many times under these circumstances, and apparently with no bad results attributable to it although some of the patients had died.

JOHN O. ROE, M.D., of Rochester, read a paper on

THE CORRECTION OF DEPRESSED AND SADDLE-BACK DEFORMITIES OF THE NOSE BY OPERATIONS PERFORMED SUBCUTANEOUSLY WITHOUT THE AID OF METALLIC OR OTHER ARTIFICIAL SUPPORTS.

He said that the operation considered in this paper was applicable to cases in which the septum is present. There are two classes of depressed noses—idiopathic and traumatic. The first class is due to lack of development of the central portion, and excessive growth of the tissues of the end of the nose. To be successful the operation must be done under the most scrupulous asepsis and antisepsis, and the after-treatment carefully supervised.

W. E. FORD, M.D., of Utica, presented a paper on

GAUZE DRAINAGE IN SURGICAL GYNECOLOGY.

He referred to the danger of iodoform poisoning from the use of iodoform gauze for drainage. His rule was to allow gauze to remain in the uterus for five days unless there was a rise of temperature and pain. He did not favor replacing the gauze. The gauze is not only useless but positively dangerous in the uterus in cases of gonorrheal inflammation. Since he had adopted the practice of curretting and tamponing before performing trachelorrhaphy, his results had been much better. In septic metritis he used a light gauze packing for not more than forty-eight hours. Recently he had found that after curetting a cancerous uterus, much comfort could be given the patient by a gauze packing wet with a solution of acetanilid. It also acted as a styptic.

DR. EASTMAN said that if gauze were used in the cervix it would, as shown by Savage, invariably cause contraction of the fundus. This would lead to obstruction, rather than drainage.

DR. H. L. COLLYER of New York said that by packing the uterus tightly with gauze the cavity would be plugged. On the other hand, if only a strip of sterile gauze were inserted drainage would be secured.

DR. DUDLEY of New York said that iodoform was more prone to absorption if used in the form of the glycerite.

W. GILL WYLIE, M.D., of New York presented some

OBSERVATIONS ON ABDOMINAL AND PELVIC SURGERY; PREPARATION, OPERATION, AND RESULTS.

His results in the last three years of hospital work were as follows: In 121 operations at Bellevue Hospital there had been ten deaths, or a mortality of 8.35 per cent. In 189 operations at his private hospital there had been three deaths, or a mortality of only 1.61 per cent.

WALTER B. CHASE, M.D., of Brooklyn presented a paper on

ABSORBABLE LIGATURES AND SUTURES IN PELVIC AND ABDOMINAL SURGERY.

He said that the qualities of an ideal ligature are sterility, pliability, strength, and endurance. Catgut, when washed in alcohol and sterilized at a high temperature and sealed in tubes, became so hygroscopic that when placed in the tissues it soon swells, filling the puncture and tightening the suture.

OBSTETRICAL DISCUSSION.

WM. WARREN POTTER, M.D., of Buffalo opened this discussion with a paper on

PUERPERAL ECLAMPSIA.

He said that the treatment should be both preventive and curative. The former should be both medicinal and hygienic, and the latter medicinal and surgical. One of the best methods of controlling the toxemia is by an exclusive milk diet, and one of the best diuretics for such cases is distilled water. When the eclampsia has become established, full chloroform anesthesia should be secured, and then, if necessary, the uterus should be promptly emptied by rapid dilatation of the cervix and the use of forceps. Cæsarean section should be reserved for extreme pelvic deformity or when the mother's condition is hopeless.

JAMES P. BOYD, M.D., of Albany, read a paper on

THE INDICATIONS FOR AND TECHNIC OF THE INDUCTION OF PREMATURE LABOR.

Premature labor should be induced in some cases of placenta previa and eclampsia in advanced disease of the heart or lungs, in hydramnios, where the fetus is dead, or when, in previous labors, the head of the child has been unusually large or unduly ossified. The speaker said that labor could be best induced by the insertion of an aseptic, flexible, solid bougie. Under the strictest aseptic and antiseptic precautions, this bougie should be inserted with the aid of Sims' speculum and a tenaculum to steady the cervix. Labor may be hastened in urgent cases by the use of Barnes' bags or by manual dilatation.

A. B. MILLER, M.D., of Syracuse, continued the discussion with a paper entitled

INFECTION OF THE PUERPERA.

He said that true puerperal infection is the result of the entrance into the birth canal of microörganisms whose habitat is outside that canal. The chief point in the treatment is to secure surgical cleanliness. Antiseptic douches destroy the germicidal secretions and act harmfully by diminishing the vital resistance, and hence the power to withstand infection.

WILLIS G. MACDONALD, M.D., of Albany, read a paper on

OBSTETRIC DELIVERY BY ABDOMINAL SECTION: INDICATIONS AND METHODS.

He said that craniotomy must be confined to cases where the fetus is already dead and the conjugate diameter is under two and a half inches. It was not nearly so safe or so simple as many claimed. Under suitable conditions, and in cases of moderate pelvic deformity, symphysiotomy would be the operation of election.

A. VANDERVEER, M.D., of Albany, presented a paper on the

PRESENT TREATMENT OF FIBROIDS ASSOCIATED WITH PREGNANCY.

He said that the subperitoneal variety of fibroid was not usually injuriously affected by pregnancy, while the interstitial or submucous variety was sometimes converted into a polypus, so that it could be easily enucleated.

DR. WILLIAM M. POLK of New York continued the discussion. He believed that when the cervical canal remained rigid in a case of puerperal eclampsia, veratrum viride and morphin would often give valuable aid. When these failed, he would advise placing the patient in Sims' position, separating the bladder, controlling the parts by clamps, and then dividing the internal os by a linear incision. Cases of pregnancy complicated by fibroids should be attacked only from above, and preferably by the Porro operation.

DR. H. J. BOLDT of New York was entirely opposed to the induction of abortion, even in the early stage of pregnancy complicated by fibroids. If at full term delivery could not be effected normally, we should at once remove the tumor and the *entire* uterus from above.

DR. C. A. VON RAMDOHR of New York favored the removal of both the uterus and fibroid by abdominal section. For a rigid cervix in a case of eclampsia, the cervix should be incised by either Polk's or Dührssen's method.

DR. A. PALMER DUDLEY believed Cæsarean section to be preferable to any other method of surgical delivery, even in cases of eclampsia. Much valuable time was thus saved, and there should be no danger of sepsis.

DR. SEARS of Syracuse said that from his own experience he could indorse all the remarks of Dr. Potter. He called attention to the danger incurred in using the curette after full term delivery. In many such cases irrigation of the uterus was much safer.

Dr. Potter, in closing the discussion, said that he regarded veratrum viride, morphin, and venesection as very dangerous, unless used with great discretion.

H. J. BOLDT, M.D., of New York read a paper on

THE CAUSES OF DEATH AFTER ABDOMINAL OPERATIONS.

He said that since the general adoption of the Trendelenburg position he believed that the mortality after abdominal operations had been decidedly increased. He had come to consider it dangerous to perform such operations shortly after a severe illness, such as pneumonia or la grippe, for undoubtedly there is more danger of septic infection, owing to the diminished vital resistance. Carelessness or ignorance in the administration of the anesthetic was probably a not unimportant factor in increasing the mortality.

EVENING SESSION.

DR. WM. HAITES of Albany made some remarks on the

PRACTICAL APPLICATION OF X-RAYS IN CASES OF FRACTURE.

He reported three recent cases in which the X-rays had rendered valuable assistance.

DR. REGINALD H. SAYRE of New York made some remarks on

POSTURE IN DIAGNOSIS OF DISEASE,

and illustrated them by lantern views.

DR. WM. JAMES MORTON of New York then gave an

X-RAY STEREOPTICON EXHIBITION.

He said that both the static machine and induction coil might be used. The coil should be capable of giving not less than an 8-inch spark. In taking a skiagraph of the hand, the source of the X-rays should be about one foot distant; for larger objects it must be further off.

SECOND DAY—WEDNESDAY, JANUARY 27TH.

To expedite the Scientific Proceedings **L. D. BULKLEY, M.D.**, offered a resolution directing the Business Committee to limit the number of papers at the annual meeting to fifty; to receive no titles of papers after December 1st unless this number had not been received, and to print on the program the time allotted each paper, this time not to exceed twenty minutes, except in the case of invited guests.

In the discussion of this motion it was opposed by **DR. ROOSA** on the ground that it would not have the effect desired by its proposer.

The matter was finally referred to the Committee on By-Laws.

DR. BULKLEY then read a paper entitled,

DEFICIENT EXCRETION FROM KIDNEYS NOT ORIGINALLY DISEASED, AND SOME DISEASES PECULIAR TO WOMEN, AND DISEASES OF THE SKIN.

This paper, he said, was so entitled as it was intended to be merely supplementary to the interesting paper on this address delivered by Dr. Etheridge last year. He had simplified Dr. Etheridge's table of the relation of the total urinary solids to the body-weight, thus: the urinary solids excreted in the twenty-four hours should amount to 500 grains for a body-weight of ninety pounds, and this amount of solids should be increased seven grains for every additional five pounds of body-weight. To determine the quantity of urinary solids: multiply the last two figures of the specific gravity by the number of ounces of urine voided in the twenty-four hours, and increase this ten per cent.

DR. HENRY R. HOPKINS of Buffalo said that it was customary for physicians to interrogate the urinary secretion in almost every other particular than in the very important one discussed in this paper.

DR. REYNOLD W. WILCOX of New York said that by this estimation of the urinary solids one could usually detect renal insufficiency long before the appearance of albumen or casts in the urine.

DR. MORTON of Brooklyn, said that eczema was (1) either purely local, or (2) was due to vaso-motor disturbance. The latter was the result of the circulation in the blood of certain toxic substances.

DR. BULKLEY, in closing, said that experiment had shown that the coloring matters and extractives constituted half of the toxicity of the urine; hence the importance of knowing the total quantity of urinary solids.

THOMAS E. SATTERTHWAITE, M.D., of New York, read a paper on

THE TREATMENT OF HEART DISEASE.

He said that absolute rest in the treatment of heart disease must soon be supplemented by either active or passive muscular movements. He preferred the use of a mixed diet, and the moderate ingestion of fluids between meals. There are three classes of Schott exercises: (1) Passive movements resisted by the patient; (2) slow, voluntary movements of the patient, resisted by the operator; and (3) an elaboration of Stoke's old method of pedestrian exercises. The Schott exercises are always gentle, and the method has the merit of being safe. The warm, saline, effervescent baths are a valuable aid to these exercises, and can be, without great difficulty, extemporized by the physician. Among our remedies, Dr. Satterthwaite still looked upon digitalis as the best. Iodid of sodium or potassium was useful, as it could be given with benefit for a long time.

DR. WILCOX said that undoubtedly the Schott baths and exercises caused a speedy diminution in the size of the ventricles. It was certainly superior to the Oertel method. But it must be admitted that the peripheral resistance could be just as well reduced by the nitrates, and the ventricles made to contract by the use of strophanthus, as could be done by the bath treatment.

DR. HENRY L. ELSNER, of Syracuse, spoke of the very common use of nitroglycerin, with a total disregard of its physiological action. It should only be used for the purpose of overcoming obstruction to the circulation. If used where the heart is weak and flabby, and the coronary arteries already dilated, the result is likely to be disastrous.

E. C. SPITZKA, M.D., of New York, presented a paper entitled

PRACTICAL POINTS RELATING TO THE DIAGNOSIS AND MANAGEMENT OF SYPHILITIC BRAIN DISEASES.

He dealt chiefly with the differential diagnosis between true melancholia and that melancholic state found in the initial period of syphilitic dementia. In true melancholia, the patient is sad because he cannot be anything else; he suffers from insomnia, and is constantly depressed; he is neglectful about his dress. In the other condition, the individual is depressed because he cannot attend to his business; he sleeps soundly at night, and often also during the day; he is inclined to be irritable, but varies greatly in temper from day to day; he is extremely particular about certain features of his dress and negligent about others. Early treatment, the speaker said, should often prove very effective. The most common error was a too exclusive reliance on the iodids, His own initial treatment was always by mercury.

DR. FREDERIC E. STURGIS of New York said that while these syphilitic melancholiacs often talked of suicide, they rarely attempted it. In his opinion, the iodids were here very much more rapid in their beneficial effects, and they also served to check the more serious subsequent symptoms.

DR. L. D. BULKLEY said that the use of mercury enabled one to greatly reduce the dose of the iodids.

DR. WILLIAMS suggested that the existence of a subnormal temperature for days together should lead to a suspicion of late syphilis.

LANDON CARTER GRAY, M.D., of New York, read a paper on

THE TREATMENT OF LOCOMOTOR ATAXIA,

to appear in next week's NEWS.

HENRY L. ELSNER, M.D., of Syracuse, reported

A CASE OF ERYTHRO-MELALGIA.

The patient experienced intense pain in the hands, so that she was even willing to submit to amputation. The erythematous spots were chiefly on the bases and tips of the fingers, but the lesion was more extensive on both thumbs. The erythema persisted, and while this was present a true Reynaud's gangrene occurred on the tip of the thumb. The only explanation he could offer for this unique phenomenon was, that where blood-vessels have been long distended, the intema becomes thickened, and finally causes obstruction and gangrene.

REYNOLD W. WILCOX, M. D., of New York, read a a paper on

STROPHANTHUS.

After studying one known and reliable variety of strophanthus—that used by Fraser in his original investigation—he had arrived at the following conclusions:

(1) Strophanthus increases the muscular action of the heart by direct action on the muscle itself; (2) its rapidity is unequaled by any other cardiac drug; (3) it has practically no effect on the size of the blood-vessels; (4) it is regularly eliminated by the kidneys; (5) unless too frequently repeated, there is no accumulative action; (6) it stands almost alone among heart remedies in acting only on the heart muscle; (7) it is about 300 times stronger than digitalin, and 300 to 400 times stronger than caffein, and, (8) it is diuretic only when the increased blood pressure invokes diuresis.

DISCUSSION ON THE RELATION OF IMPURE DRINKING WATER TO DISEASE, AND THE CURE AND PREVENTION OF THE LATTER.

GEORGE BLUMER, M.D., of Albany, opened this discussion by a paper on

DISEASES WHICH CAN BE DIRECTLY TRACED TO CONTAMINATED WATER.

He said that the diseases due to animal organisms in water were malaria and amebic dysentery, although the evidence in the case of malaria is not very conclusive. The diseases due to vegetable organisms are typhoid fever, Asiatic cholera, and certain diarrheal diseases.

ROWLAND G. FREEMAN, M.D., of New York continued the discussion with a paper on

DANGERS OF THE DOMESTIC USE, OTHER THAN DRINKING, OF CONTAMINATED WATER.

He said that in eleven epidemics of diphtheria caused by milk that he had collected, in two it was supposed to have arisen from the use of contaminated water on the farms. In fifty-three epidemics of typhoid fever due to milk, in nine it was found to have originated in foul water. The danger of typhoid fever being disseminated by oysters had been known only since 1894. The typhoid bacillus will live for eight days in water taken from oyster-beds. If injected in oysters these bacilli may be found for thirty days.

T. B. CARPENTER, M.D., of Buffalo read a paper on the

METHODS OF PURIFICATION OF IMPURE WATER.

He said that in practice sand filters had recently been proved to be quite efficient. Mechanical filters, to be efficient, must be used with some coagulent, such as alum.

The following officers were chosen for the ensuing year: President, Seneca D. Powell, M.D., of New York; Vice-President, Lucien Howe, M.D., of Buffalo; Secretary, Frederic C. Curtis, M.D., of Albany; Treasurer, Charles H. Porter, M.D., of Albany. The chairmen of the various committees were all re-elected.

(To be continued.)

THE MEDICAL NEWS.

A WEEKLY JOURNAL OF MEDICAL SCIENCE.

VOL. LXX. NEW YORK, SATURDAY, FEBRUARY 6, 1897. No. 6.

ORIGINAL ARTICLES.

SOME CLINICAL CASES OF DISEASE OF THE TESTICLE.[1]

BY L. BOLTON BANGS, M.D.,
OF NEW YORK;
CONSULTING SURGEON TO ST. LUKE'S, THE CITY, AND THE M. E. HOSPITALS; VISITING GENITO-URINARY SURGEON TO ST. MARK'S HOSPITAL; FORMERLY PROFESSOR OF GENITO-URINARY DISEASES IN THE N. Y. POST-GRADUATE MEDICAL SCHOOL AND HOSPITAL.

THE diagnosis of disease of the testicle is not always clear. The history is frequently inexact, and pathological conditions which differ widely from each other oftentimes have the same appearance and give the same sensations to palpation. Often it is only after repeated and frequent observation of the case, or after the appearance of a positive pathological condition which differentiates the disease, that a diagnosis is made. On the other hand, it may happen that no diagnosis can be made until after some operative procedure, either one which is simply exploratory, or one which involves the excision of the organ, and this delay, necessary perhaps, may jeopardize the life of the individual. To illustrate these points I beg leave to present for your consideration the following group of cases. The first one, which was marked by extreme suffering, presented no salient diagnostic features, and was only elucidated after the organ had been removed.

The patient, a man aged fifty-four years, came under my observation three days after the beginning of pain in his left testicle. He gave a history of having had several attacks of gonorrhea, the first one thirty-five years previously, and six subsequent attacks. They pursued the ordinary course, and I doubt if the man was ever entirely free from urethral discharge. He was a steady drinker but not an inebriate, according to his own story. His last attack of gonorrhea had occurred three years before he came under my observation, and about that time he had an internal urethrotomy performed by one of my colleagues. Three days before I saw him, after a long walk (to which the patient attributed the commencement of his malady), his left testicle increased in size and became more and more painful. The pain was so severe that it interfered with his work, and he entered the hospital. An examination disclosed that the left epididymis and the testicle proper were twice the normal size, hard, and extremely tender; the tissues of the scrotum were livid and edematous. There was no acute urethritis present, and he gave no history of syphilis or of traumatism. The man's general condition was good, his right testicle was normal in size, and although the suspicion of tubercular inflammation was suggested, there was nothing to confirm it. He was put to bed and simple treatment by suspension and poulticing was instituted, but the patient suffered intensely and could only be relieved by opiates. The temperature rose to between 102° and 103° F. Ten days later, all treatment having proved unavailing, the patient was anesthetized, and suspecting pus in the tunica vaginalis, I laid the latter open. A small quantity of pus exuded, together with layers of fibrin and small clots, which inclined me to the belief that I was dealing with an old hematocele. The wound was left open and dressed in the usual antiseptic manner. The operation only partially relieved the patient; he still complained of pain which again increased in intensity, and in spite of the administration of opium he suffered very much. The testicle was examined from time to time to see if any pus remained in the cavity of the tunica vaginalis, or if there were any local accumulations in the scrotum, but none could be found. The testicle proper continued to be intensely painful, exquisitely sensitive to manipulation, but no special point of pain or of fluctuation, or even of tension, could be ascertained. Accordingly, nine days later he was again anesthetized and the testicle removed. The visceral layer of the tunica vaginalis was very much thickened, and in making an incision through this between the epididymis and the body of the testicle was found an accumulation of pus shaped like a cone with its apex downward, accurately circumscribed and held in place by the thickened tissues.

The pathologist's report was as follows: "The vessels in the testicle and epididymus are dilated, and at numerous points red blood corpuscles have escaped and are extravasated through the inter-tubular connective tissue. Some of the seminiferous tubules contain red blood corpuscles. There are also numerous areas of round-celled infiltration, often coincident with the areas of extravasated blood corpuscles. The tunica vaginalis is thickened and covered by an inflammatory exudation, composed of fibrin and red and white blood corpuscles. In the sub-serous connective tissue there are small masses of blood pigment, evidently the result of previous hemorrhages. The anatomical diagnosis is acute inflammation of the tunica vaginalis, with hemorrhages old and recent, with secondary inflammatory areas in the testicle and epididymis."

It was evident, both from the macroscopic and microscopic appearances, that an inflammation of some intensity was the origin of this man's suffering, and that the exudation upon the serous membrane had strengthened or fortified it to such a degree that pus between the testicle and epididymis could not escape. The pressure and presence of the pus produced such a degree of suffering that, in the absence of any means of locating it, I do not think any relief could have been obtained without removal of the entire organ.

---

[1] Read at the meeting of the New York State Medical Society, Albany, January 27, 1897.

The cause of this man's orchitis was not clear to me. It reminded me, however, of a case, which I reported some years ago, of a man who denied ever having had a urethritis. He came to me with an inguinal hernia, which I decided to operate on. The hernia was complicated by an undescended and inflamed testicle, which had to be removed. On severing the vas deferens there was a little spurt of pus, which, unfortunately, was lost, and no examination for gonococci could be made. Within twenty-four hours the patient developed an acute urethritis, which had evidently been latent until the operation. With this fact in mind, it may not be unreasonable to assume that the other patient also had a latent gonorrhea, which was excited into activity by his long walk, and which was responsible for the inflammatory foci in the epididymis and testicle.

To emphasize the point that in some instances no positive diagnosis can be made until an operative procedure is instituted, take the following case, which, apparently serious, proved to be very simple:

A man aged seventy-three. Up to a few weeks before coming under my observation the history was that of simple hydrocele, which had been tapped, and as he described it, a light, watery fluid had been drawn off. This procedure had been repeated a few times, whenever the increase in size of the scrotum interfered with locomotion, but latterly the fluid obtained had been bloody. Early in the history there had been no pain. Recently, however, the scrotum had become very dark in color, and had grown "hard," and pain had developed in the left testicle, running thence up into the groin. Two weeks before, an attempt had been made to tap it as on previous occasions but no fluid had been withdrawn. Pain persisted, the testicle increased in size, and the old gentleman became prostrated, and was obliged to take to his bed. He was then sent to me with a letter from his doctor, a gentleman of hospital training, with the statement that he suspected that malignant degeneration had taken place in the testicle.

His condition, as nearly as can be described in words, was as follows: There was no rise of temperature; he was pale, anemic, and so weak that it was with difficulty he walked into my office. His scrotum, the whole of it, was enormously enlarged—more than double its normal size, edematous, and of a purplish hue; the left half, particularly, was hard, with intervening soft areas, and very sensitive. Here and there it looked as if the tissues of the scrotum were infiltrated and would speedily break down. The right testicle could be distinguished, and was pushed upwards and outwards by the swelling of the left side. The left side of the scrotum was an indefinable mass, extremely sensitive on palpation, and no satisfactory examination could be made. The cord could be felt enlarged in the inguinal region, and was also sensitive. The tumor was not translucent, even to the direct rays of strong electric illumination. The history, to my mind, pointed more to some inflammatory process than to malignant disease, but it was impossible to make any definite diagnosis, and for a few days he was subjected to tentative treatment, without avail. Then he was placed under ether and a long incision made over the tumor. It was found that a sero-hemorrhagic exudation had taken place into the tissues of the scrotum, but no pus was detected. The tunica vaginalis was found to be much thickened, and filling its sac were several layers of a soft, fibrinous exudate and broken-down blood-clots. This adventitious material, together with a few calcareous plates, which were found on the parietal surface of the tunica, was thoroughly removed by a dissection which included portions of the serous membrane. The testicle itself was found crowded downward and backward by the exudate, but was normal, and was replaced within what was left of the sac. The wound was sutured, drained for two days, and healed without suppuration. There were no adverse symptoms, and the patient was discharged twelve days later.

As is evident, the operation not only cleared up the clinical features of this case and cured the patient, but threw light upon the etiology. Without doubt the whole process had been caused by the later attempts at tapping which had not only injured a vessel but had infected the tissues enough to set up the inflammatory hyperemia, without as yet producing pus.

In contrast with the case which I have just narrated consider this one:

A young man of thirty years whose general health had always been good, came under my observation in October, 1890. His history was very brief. In June and July of that year he had been under treatment for what was called "an enlarged testicle," for which no cause could be assigned. There was no history of traumatism and no antecedent urethritis. He remained under treatment for three weeks at a hospital, and was then discharged. As he had been under the observation of competent men the probability is that at that time there was no suspicion of the nature of the disease. He stated that after leaving the hospital the testicle increased in size, but it was not painful, and did not interfere with his general well-being. Of late he had observed that when irritated, as he described it, by undue exercise—a long walk, for example—it seemed to increase somewhat in size, but there was no spontaneous pain in it. On examination it was found that there was no discoloration of the scrotum. The tissues of the latter were normally movable and were not infiltrated. The whole testicle was uniformly enlarged to about three times the size of its fellow; it was distinctly pulpy on palpation, and pain could be elicited on the slightest pressure. It was not translucent. There was slight enlargement of the cord. There was no enlargement of the inguinal glands and no glandular enlargement could be made out by palpation of the abdomen.

The progressive increase in size of the testicle without pain and without signs of inflammation, and especially its uniform softness as contrasted with other pathological conditions (*e. g.*, syphilis, tubercle) led me to the conclusion that it was of malignant character and should be removed at once. Accordingly, the testicle was excised, the inguinal canal being laid freely open and the cord divided as high up as possible. The wound healed by first intention, although there were a few points of suppuration in the stitch-holes. The patient was discharged cured on the fourteenth day. The pathologist's report showed characteristic carcinoma of the epithelial variety.

I kept this patient under observation. In July of the following year he had an abdominal tumor develop which was located in the left hypochondrium, extending toward the ensiform cartilage. It was hard, smooth, painful, and dull on percussion. It was firmly attached, but could be displaced laterally outward, and not downwards.

Here, evidently, was a speedy relapse which an exploratory incision, made in the hope of removing the mass, proved to be in the kidney of that side, and in the abdominal glands. The recurrence in the abdominal glands and not in the inguinal ones was confirmation of a fact which was fully brought out in a discussion of this subject at the ninth annual meeting of the American Association of Genito-Urinary Surgeons, held at Niagara Falls in May, 1895.

The latter case is in strong contrast with the preceding one as to age, the appearances of the tumor, and as to the final result. In the old man, pain, persistent and severe, was a prominent factor. In the young one, there was no spontaneous pain, there was no discoloration of the scrotum, and the tumor was soft, whereas in the old man the tumor was hard, and its naked eye appearance might be termed decidedly "malignant." Yet in the case which appeared to be the most severe, the disease proved to be benign, while in the other it was rapidly fatal.

In corroboration of the fact that a case apparently benign may have elements of malignancy and demand radical methods, take the following:

A young man, twenty-three years of age, was brought to me with the following history: When about thirteen years of age he was struck by a baseball on his left testicle, and four years later he fell astride a fence and bruised the same testicle. Following the first traumatism a moderate sized "lump" appeared at the bottom of the left testicle. It was not painful and never had been until two or three weeks before he came under observation, but it had grown slowly in size, and during the past year its growth had been more rapid than during the previous nine years. There was no history of an abnormal growth in any other member of his family. The patient, whose general health had always been good, gave no history of any urethral disease, but about a year before he came under my observation he had had a "sore" at the end of his penis, in regard to which there seemed to have been some doubt. At all events, it was treated by caustics and he had some form of internal treatment for four months. No symptoms referable to the sore followed. The right testicle was normal. At the base of the left testicle and attached to it by a pedicle, was a hard, firm tumor, insensitive on palpation; its circumference (the measure including the tissues of the scrotum which covered it) was 4¾ inches; the pedicle seemed to be a little over an inch in length and was exceedingly sensitive; it apparently sprang from the tunica albuginea, and had no relation to the epididymis.

The history of a slowly growing, painless, insensitive, and hard tumor, not a part of the testicle but springing from it, led me to the diagnosis of a fibroma, but the recent rapid increase in size and the accession of pain made me suspicious that it was undergoing some form of degeneration. Accordingly, I took him into the hospital with the intention of removing the tumor only and leaving the testis, if possible. Upon cutting down upon the tumor, the latter was found to spring from the posterior aspect of the body of the testicle and from the cord. Its surface was slightly irregular or nodular, and its pedicle seemed well supplied with vessels. Appreciating that the growth was one which might easily degenerate into some form of malignancy, I decided that it was best for the patient to remove the testicle also. This was accordingly done. The growth was subjected to the pathologist, who reported: "It is a pedunculated tumor, one inch in diameter, very firm, and white on section. Microscopic examination shows it to be a fibroma. *The tissue has in places more cells than in ordinary connective tissue, but not enough to put it among the sarcomata.* The testicle is normal."

This statement of the pathologist taken in connection with the recent clinical history of the patient, and with what is known of the pathological tendencies of the testis, seem to me to warrant the radical treatment which was adopted rather than to have the patient take the risk of further and dangerous involvement.

The Ventilation of Passenger Cars.—It is estimated that to keep a coach containing sixty persons fully supplied with pure air the atmosphere would have to be changed every eighty seconds, or something like forty-five times each hour. It is found practically impossible to raise air from zero to a comfortable temperature with such rapidity, and in consequence a compromise between bad air and low temperature is essential in cold weather.

THE TREATMENT OF DIPHTHERIA WITH ANTITOXIN.[1]

BY JOSEPH H. LOPEZ, M.D.,
OF PHILADELPHIA.

OF the many recent discoveries, none has provoked more controversy than diphtheria antitoxin, in which respect it bears a strong resemblance to vaccination. Able men have written pro and con on the subject, both sides being governed by honesty of purpose, but each, as is human, viewing the subject from his own standpoint. Men are broader and much more liberal in their views to-day than they were in olden times, which tends to give both length and breadth to a controversy. In the days of Jenner, prominent men wrote in fierce condemnation of what they termed the vagaries of vaccination, and were in turn the recipients of congratulatory letters from others equally as prominent as themselves. In face of all this, Jennerism has stood as the triumph of a century. In the present discussion, men of undoubted ability are arrayed against antitoxin, but their number is small. In striking contrast with these is a class more numerous, who evince by their writings total ignorance of the subject, and are guided solely by their prejudices. In an age so liberal as this, an open discussion serves to bring to the surface the true merits of a remedy, and facilitates in giving it the proper place in therapeutics.

Through the courtesy of the H. K. Mulford Company, I was permitted to visit their biological laboratory and witness the process by which diphtheria antitoxin is secured. Of this privilege I heartily availed myself, in order to obtain the data for this paper. To understand how antitoxin is produced, it is necessary to have a clear conception of five terms. These are: *germs*, *toxins*, *serum*, *antitoxin*, and *units*. They must be clearly distinguished, one from the other. Antitoxin (upon which alone depends the efficacy of the remedy) is one thing, and serum (its vehicle or menstruum) is another. Antitoxin does not exist in any appreciable measure in the blood of the horse until it receives the treatment which will be described in this connection.

The germ of diphtheria is the specific cause of the disease, while the toxin is a complex poison produced by the germs. If germs of diphtheria are injected into a susceptible animal, they will produce diphtheria; if toxins are injected, they will cause acute poisoning. In the laboratory the toxins of diphtheria are separated from the germs by a very delicate filtering process. The toxins only are used in treating the horse that is to yield the antitoxin. It will thus be observed that the injections do not produce diphtheria in the horse. They could not do this, for the germ which is the sole cause of diphtheria was first removed. The toxins separated by the process of filtering must conform to a certain high standard of virulence or be rejected. This standard is obtained by experimenting on guinea-pigs. It must be so toxic that an injection of three-tenths to 1½ minims will prove fatal within thirty-six hours. This quantity is called the minimum fatal dose. One standard or immunizing unit indicates that potency of a given quantity of antitoxic serum which will neutralize ten times the minimum fatal dose of standard toxin in a guinea-pig.

If a moderately large dose of toxin were injected for the first time into a horse, it would sicken and die. The initial dose, however, is made very small, only 10 or 15 minims being given. This dose is gradually increased and repeated at intervals of six or eight days, for about three months. While the horse is found to fret considerably after the first dose, at the close of the period of treatment, when a trial bleeding is made, he will receive an injection more than three hundred times as large as the first one with impunity. During this treatment nature's antidote against the poison injected is poured into the blood in such quantities as to make the serum of this blood a remedy *par excellence* against the same poison in the system of the victim of diphtheria. If the trial bleeding shows the presence of sufficiently large quantities of antitoxin, the animal is freely bled and the serum separated. When this is carefully preserved against putrefaction and other bacterial contamination, and the unit strength ascertained, the remedy is ready for use.

In the treatment of diphtheria the most important step is to make an early diagnosis, and the next is to give antitoxin in sufficiently large doses as soon as the diagnosis is made. You are all familiar with the characteristics of typical diphtheria. The whitish-gray, leather-like membrane, superimposed apparently upon the mucous membrane, attended by fetor, and tending to become darker as it spreads and the malady progresses, can tell but one story. My observation is that the more rapidly the membrane spreads, the more malignant is the type of diphtheria, and the greater the danger from early toxemia. To illustrate the process of invasion and the physiological effects of antitoxin, I beg to cite a case of more than usual interest as regards the rapid extension of the membrane (See illustration), as well as the prompt and decisive action of antitoxin.

The patient, a girl of five years of age, was brought to my office September 10th, at 7.30 P.M. Examination of the throat revealed a small white spot on the right tonsil (Fig. 1). The following morning this white patch had extended, forming a continuous white line from the right tonsil across and around the uvula to the left tonsil (Fig. 2). The diagnosis was evident. I subsequently learned that another child, a boy of seven years and a brother of my little patient, had died from diphtheria after three days' illness, and was buried the day I first saw the little girl. A 5 P.M. I injected 1000 units of Mulford's Potent Antitoxin; at 10 A.M. of the following day the grayish-white line was displaced by a red line (Fig. 5), the red line of demarcation indicating that the healing, or neutralizing, effect of the remedy had commenced. When this red line was once gained, the membrane disappeared as rapidly as it had appeared. At 5 P.M. of the same day fully one-third had disappeared, while after twenty-four hours, scarcely a trace remained. All the symptoms began to ameliorate within twelve hours after giving the injection. Only one injection was found necessary. The supplementary treatment was that which I generally employ. This consists of calomel in repeated doses till the alimentary tract is cleared, sprays of peroxid of hydrogen, stimulants, and general tonics, according to the special indications of the case.

---

DIPHTHERIA IN A CHILD AGED FIVE YEARS, SHOWING RAPID GROWTH OF MEMBRANE ON TONSILS, UVULA, AND SOFT PALATE, AND ITS SUBSEQUENT RAPID DISAPPEARANCE UNDER THE USE OF ANTITOXIN.

In the laboratory the curative dose required to save a guinea-pig is determined by mathematics. Both the quantity and the virulence of the diphtheria toxin floating in the blood current of the animals are accurately known. From these factors the bacteriologist readily determines the number of immunizing units needed to save the animal. In clinical practice the physician has no power to determine either the amount or the virulence of the toxin absorbed into the system. He has not even the power to make an approximate estimate. All he can know is that, all else being equal, the more extensive the local lesion the more profound will be the degree of toxemia resulting and the earlier will fatal toxemia appear. Because of this it follows that the initial dose of antitoxin should be efficient. Antitoxin is an innocuous therapeutic agent. Should the dose be more than is absolutely needed, no harm will follow. The case will be fully met and but one injection be needed; on the other hand, if the dose is inadequate, the unneutralized toxins may go on to produce fatal results. It is not well to rely solely upon antitoxin, since there are always indications for treatment which can only be met by other remedies. In two of my most malignant cases, however, I had to rely entirely on the antitoxin, as the stomach was too irritable to bear either food or medicine. Though the patients (three and five years of age) were much depressed by the disease I injected in each case in two doses, with an interval of twelve hours, 2500 units of antitoxin. Besides this I used only the spray of peroxid of hydrogen, until tonics and stimulants could be retained. The recovery was complete in both cases and without interruption, but less rapid than when the antitoxin was administered in sufficient doses in the early stages of the disease. In the early stage from 600 to 1000 units is usually sufficient, but when seen in an advanced stage 2000 units should be injected at once, and the dose repeated in ten or twelve hours, if the progress of the disease is not arrested. The danger from diphtheria in advanced stages is great, but there is no danger from an overdose of antitoxin if a reliable preparation is used.

From the report of the American Pediatric Society on the use of diphtheria-antitoxin, published in the MEDICAL NEWS July 4, 1896, I take the following: "One of the most striking features, developed by the collective investigation committee, is the widespread employment of antitoxin (over 600 physicians submitted reports). The general inference to be drawn from the report as a whole is that the antitoxin treatment of diphtheria has proved so efficient that there is no longer any doubt of its permanency as a therapeutic measure, but that it bears two pronounced elements of uncertainty. The first is the amount of the dose; and the second, and still more important one, the quality of the serum."

From the MEDICAL NEWS, December 19, 1896, I quote the following: "The MEDICAL NEWS purchased nineteen different samples of serum (foreign and American) in the open market, in six different cities of the Union. After the labels had been removed and numbers substituted, they were submitted to Professor A. C. Abbott of the University of Pennsylvania for examination." From Professor Abbott's report I condense the following: "The majority of the samples exhibited the average required strength. Four were unusually rich in protective substance, while in three there was a relative deficiency of antitoxic properties. Some of the samples proved to be of unusual strength, while others were shown to be so poor in antitoxin as to demonstrate their comparative uselessness for therapeutic purposes. In some instances there was great discrepancy in the actual strength and in the advertised strength. Certain of the samples from the same manufacturer, purchased in different markets, at the same and different dates, showed a wide variation; other samples retained their strength absolutely from three to twelve months, while some contained only about two-thirds of their original strength at the end of three or six months."

Thus we have an explanation of the conflicting results published of the antitoxin treatment, apart from the question of *time*, *quantity*, and *method* of administration.

The Health Bulletin of the Tennessee State Board of Health, commenting on the investigation of the American Pediatric Society, says: "The report affords very strong testimony in favor of the treatment of diphtheria with antitoxin. The grand total gives 5794 cases, with 713 deaths—a mortality of 12.3 per cent., including every case returned; but excluding 218 cases that reports show were moribund at the time of the injection, or died within twenty-four hours of the first injection, there remained 5576 cases, with a mortality of 8.8 per cent. Of 4120 cases injected during the first three days, there were 303 deaths—a mortality of 7.3 per cent., including every case reported; but if from these we deduct the cases which were moribund at the time of the injection or died within twenty-four hours, we have 4013 cases with a mortality of 4.8 per cent. Behring's original claim that if cases were injected on the first or second day that the mortality would not be more than five per cent., is more than substantiated."

In conclusion, permit me to say that, to save your time, I have selected only the prominent points and deductions from the above reports, and have endeavored to present them as briefly as possible for your consideration. While my personal experience with antitoxin can add but little to the many cases recorded, yet I would state that for some years I have been associated with three institutions, containing in all about 800 children. I have thus been afforded the opportunity of witnessing the effects of many remedies suggested for the cure of diphtheria, and must say that, in an experience of over twenty years, no other remedy I have ever employed gave such prompt, marked, and lasting results as antitoxin. The characteristic red line which makes its appearance after the successful injection of antitoxin is of great significance. It enables the physician confidently to assert that the disease is checked, and the poison which threatened life neutralized.

Such has been my experience with antitoxin, though limited to thirty-seven cases, with perhaps more than double that number of immunizing doses administered. Of the former, all recovered excepting three, which occurred in one of the asylums, in cachectic children, closely following a grave type of measles. These did not seem to be affected by the antitoxin, but rapidly progressed to a fatal termination. In the other cases, a general amelioration of all the symptoms was noted early, and the progress to recovery was both speedy and complete. With few exceptions, but one dose of antitoxin was required. Of those immunized, not one contracted diphtheria. As I invariably resort to immunization, it has been my fortune not to have a second case of diphtheria in the same family since using antitoxin. In one instance, after drawing the usual curative dose into the syringe, I found a small quantity of antitoxin (about 250 units) remaining in the bottle. This was enough to immunize the only other child in the family. After carefully sterilizing my syringe, I injected it into the little fellow, with the happiest results. In six cases, the respiration was so greatly impeded when I first saw them that intubation was necessary to prolong life and give the antitoxin time to act. Four of the six cases recovered.

In view of the results of the examination of the antitoxin, as published by the MEDICAL NEWS, the physician can not be too careful in the selection of his antitoxin. When one physician requires from two to ten injections to do what others can accomplish with one or two, the fault must be with the product he is using. Whilst it would have been of great value had the MEDICAL NEWS published names with the results of its investigation, we must infer that there were good reasons for withholding them. We can therefore only express our appreciation of the good work accomplished. My own experience is restricted to American antitoxin. I have used Parke, Davis & Co.'s, and H. K. Mulford Co.'s, and found them both efficient and reliable, and in view of the results of the bacteriologic examination as conducted by the MEDICAL NEWS, I have no inclination to "grope in the dark" by making a change. The latter house has introduced a highly concentrated serum which I prefer since it removes all objections to the serum treatment, due to the large quantity of serum to be injected, and is in my opinion, the greatest improvement yet made in diphtheria antitoxic serum.

DIASTASE IN THERAPEUTICS.[1]

BY C. C. FITE, M.D.,
OF NEW YORK.

THE sprouting of a seed was considered, until quite recent times, a great mystery; not until diastase was discovered could we properly understand why a seed after being placed in a moist soil began to develop into a plant after having lain dormant perhaps for years. Under proper conditions, the life endowed germ is no longer a sleeping unknown quantity, but is an active principle, and the process of development begins.

The sprouting of seed is a very interesting subject for scientific study—this awakening of the germ life, by the influence of heat and moisture, as is the action of diastase in converting the starch of the seed into maltose, which afterwards becomes fibrous or cellular tissue. We will not go into a discussion here in reference to the secretion by the plant of fluids which, acting through the delicate roots, absorb and utilize the soil elements; of the important work done by the leaves in taking carbon from the atmosphere; and by these and other processes completing the growth of the plant and eventually reproducing the seed to continue the life of the species indefinitely.

Let us now leave the plant and refer to the important factor in the growth and development of animal life—the ptyalin of the saliva, a product analogous in many respects to diastase. Just as nature places diastase in the grain to produce the changes leading up to a higher growth, so she gives animals ptyalin to convert the starch and perhaps other foods into assimilable material for nourishment, for heat, and a reserve supply of fat. I use the words nourishment, heat, and fat, advisedly. The starch so converted is nourishment, and it is the basis of our caloric energy. Our supply of fat comes mainly from the starch changed into maltose by the ptyalin, supplemented by the pancreatic secretions, and it is changed into oil later on in the process. This oil is not only utilized for heat but stored in the tissues as a reserve supply.

It is well to bear in mind that few carnivorous animals take on a great degree of fat; grain eating animals do. Give swine all of the fat and oils they can eat, and they will not gain in weight half as quickly as when fed on grain alone.

The function of ptyalin is to convert starch into dextrin and maltose, this being the preliminary step, and it goes on in the normal stomach for from thirty to forty minutes after the close of an ordinary meal, when the acid peptic digestion stops the diastasic process. The duodenum holding the pancreatic and other secretions takes up the partially changed starch and completes the conversion. We need not follow the process beyond this point.

It has long been observed that we do not get altogether satisfactory results in the treatment of amylaceous indigestion with pancreatic extracts. This is probably due to the fact that the amylopsin of the pancreatic juice and the various other duodenal enzymes are intended more for completing and finishing the changes already begun by ptyalin before the peptic digestion supervenes, and are not adapted for this preliminary conversion in the stomach. In other words, they are not suitable for beginning the conversion in the food mass as found in the stomach—acting, we might say, on the mass later when it is an acid body, during the time it is being changed from an acid to an alkaline reaction, instead of on the alkaline or neutral mass when it is being changed into an acid mass. We see, therefore, that while ptyalin and amylopsin are practically identical in their action on starches, nature intends them to act under different conditions and at different periods of the digestive process. Therefore, we should not give pancreatic extracts with the expectation that they will render desirable service in the stomach, but should rely either upon increasing the supply of ptyalin by slowly masticating the food, or by giving a ferment having similar properties to ptyalin; this we have in diastase.

---

[1] Read before the New York Medico-Surgical Society, January 4, 1897.

From the time of the discovery of diastase in malt until quite recently, many attempts have been made to produce it in an isolated form economically enough to be used freely in medicine, without having to give it in the form of the semi-solid malt extracts which has been the only reliable form of it readily obtainable by the profession, as the liquid malt extracts do not contain an appreciable amount of diastase.[2] The disadvantage in its use in malt extracts is that we have to give a large bulk of the extract to get a very small quantity of diastase; then too, the extract contains fermentable sugars and extractive matters which may not only be of no value, but may give rise to fermentation in the stomach or intestinal tract.

So far the only person who has succeeded in producing an isolated diastase economically and on a large scale, is Jokichi Takamine, the Japanese chemist, (*London Lancet*, May 25, 1896). This investigator received his scientific education at the Glasgow University. He devoted some years to the study of malting and the production of diastase and other ferments, and upon his return to Tokio was fortunate enough to find that Eurotium oryzæ was what he desired. The process he finally perfected is in brief as follows: The seed of the Eurotium is sown on moistened and sterilized wheat bran. The growth is rapid, and after the plant has reached maturity he calls the bran with the growth on it "Taka-Koji." Upon examining this growth under the microscope it is found that the roots of the Eurotium which have penetrated the bran are covered with crystals of pure diastase. These diastase crystals have the property of converting the starch of the bran for the nourishment of the plant. Takamine named the diastase so produced, Taka-diastase. In preparing this diastase for use in medicine it is necessary to get rid of the spore. This is done by percolating the Taka-Koji with water, and adding to this solution of diastase, alcohol, when the diastase is precipitated and the activity of the spores destroyed. It is then a simple matter to further purify the diastase and preserve it in a dry powdered form indefinitely.

This diastase, owing I presume to it being an isolated substance, acts much quicker than the diastase found in malt extracts. It will convert 100 times its weight of starch in ten minutes under proper conditions; if the process is continued for three hours, 1500 times its weight. It is therefore evident that its amylolytic-converting power is quite marked, and the theoretical position that it would prove of value in the treatment of amylaceous indigestion has been verified by careful observers many times over.

Professor Leo, of Bonn, claims that this diastase exerts its action in a higher degree of acidity than was first claimed by those of us who had experimented with it, and that it is, therefore, superior to ptyalin in its starch-converting power. He has employed it with benefit in cases of deficient salivary secretion, and also in hyperacidity of the stomach.

Dr. W. S. Christopher, of Chicago (*Therapeutic Gazette*, March, 1896), holds that flatulence is due to microörganisms which attack unchanged starch and give rise to fermentation, and that it is therefore important in these cases to pre-digest the starch in the stomach, and the more complete this process, the less food there is for the microörganisms to act upon in the duodenum. He finds that the administration of diastase in these cases gives satisfactory results.

Dr. R. W. Wilcox, of New York, has given very close attention to the therapeutics of this question, as shown by two papers he read some months ago, one before the New York State Medical Society, January, 1896, and one before the New York Academy of Medicine, February 18, 1896, both papers being published in the MEDICAL NEWS.

Other favorable clinical reports which have attracted my attention, which may be mentioned here, were published in the *Journal of the American Medical Association* for August 15, 1896, by Dr. T. H. Allen; in the *Medical Age* for July 25, 1896, by Dr. F. Spencer Halsey, and in the *Therapeutic Gazette* for September 15, 1896, by Dr. Wm. A. Walker.

In the practice of some friends, who have reported the matter to me for elucidation, this form of diastase seems to have other properties than its action on starch. In one notable case in which pepsin and other methods of treatment failed to give any benefit, although every symptom and test seemed to indicate that it was an undoubted case of albuminous indigestion, the result was not only palliative but curative. I have endeavored to have this matter settled by laboratory experiments, but so far the results have not been entirely conclusive, so any theory on this question for the present must be based mainly upon clinical evidence. This diastase does, as was shown by the experiments referred to, *disintegrate* albumens, but the proteolytic action *apparently* stops short of the production of albumoses and peptones. As to what takes place in the intestinal tract of course we cannot yet say. It is altogether probable that the benefit in these cases is due to the promptness with which the first period of digestion is carried on and the conversion, instead of the fermentation, of the starchy foods, leaving the second process, the acid peptic digestion, to go on normally without being interfered with by deleterious products; and the partial disintegration above referred to doubtless promotes the activity of the gastric juice by giving it freer access to the particles of albumen.[1]

---

[2] *Boston Medical and Surgical Journal*, December 31, 1896, p. 669.

We should always bear in mind that we have from thirty to forty minutes after the close of an ordinary meal in which the action of ptyalin or diastase will continue before the acidity of the stomach contents reaches the point at which such converting power is impaired or destroyed. The proper theory for the administration of diastase is that it supplements the ptyalin of the saliva, and the more thorough the preliminary digestion in the stomach, the less work there is to be done in the duodenum. The formerly prevalent theory that pancreatic extracts and diastase ought in some mysterious way to find their way through the stomach into the duodenum, and there begin their work, is too absurd to be entertained. (See Dr. Walker's article above referred to.) I am indebted to Dr. Henry Dwight Chapin for information in this connection (*N. Y. Medical Journal*, September 16, 1893), the results of some elaborate experiments which he had made in the Post-Graduate Laboratory in 1893. The experiments were made with a product containing diastase; the stomach was washed out, and after the subject had been properly fed the diastase was administered in certain cases and omitted in others. The report made to Dr. Chapin by the chemist in charge of the work was, that, when the stomach was emptied forty minutes after the administration, the percentage of food remaining in the stomach at this time averaged, when diastase was not given, 52.02 per cent.; with diastase, 29.2 per cent. This showed very conclusively the action of the diastase in the stomach. An analysis of the solid food remaining in the stomach showed that when diastase had not been administered 7.02 per cent. was undissolved; when it was given, only 3.45 per cent.

Experiments with diastase have not up to this time been as satisfactorily conducted as those made with pepsin, for the reason that diastase is a sensitive body, and the value of any laboratory or test-tube experiments is apt to be contradictory, unless proper precautions are taken as to the degree of heat used, and because the various brands of starch found in the market vary in reaction and in their sensible properties. It is to be hoped that we will soon have definite tables in use for this work, so that all experiments being made by a uniform standard the results can be more intelligently compared and studied.

I might add in conclusion that the therapeutic properties of diastase have not yet been as thoroughly investigated as could be desired. A good deal of careful work is now being done by investigators in this and other countries, and I am confident that the literature of the subject will be enriched very greatly in the near future.

So far little has been done with diastase in practical medicine beyond its use in typical cases of amylaceous indigestion. What we may expect from its employment in partially converting the starch of barley water for infant feeding remains yet to be determined, but I am very hopeful of its use in such cases. The fact of the casein of cow's milk being so much more dense and liable to form tough curds than human milk, has led me to hope that if we partially convert the starch of the barley water, it will become not only a mechanical diluent for milk, but a readily absorbable food as well, which will nourish and not give rise to fermentation and flatulence.[1]

Some time since I witnessed several experiments in bread-making made by Mr. C. Von Egloffstein, then of Yonkers, now of Brooklyn, N. Y., to determine the value of diastase in rendering bread more soluble. His conclusions were that the soluble matter in ordinary bread in water at a temperature of 100° F. represented at the end of an hour fifteen per cent., whereas when a proper amount of a product containing diastase was added to the bread before baking the soluble matter under the same conditions was forty per cent.

It is more than probable that diastase will play an important part in the therapeutics of the future.

ABSTRACT OF DISCUSSION.

Dr. W. L. Stowell: I wish to express my pleasure at listening to this paper. For the last five or six years I have been greatly interested in the various forms of indigestion and the remedies supposed to overcome them. Most of the diseases we are called upon to treat, if not due to direct infection, are due to some difficulty in the digestive tract. These difficulties are either fermentation from pathogenic organisms or deficiency of digestive ferments. Antiseptics, while they prevent the formation and development of germs, and so prevent indigestion to some extent, do not assist the digestion of food in a weak digestive tract. Therefore we need to help the patient by first selecting suitable food, and secondly, by helping him to digest what food is taken in. Patients who complain of bloating and pressure an hour or two after meals, and who complain also of constipation most of the time, can, as a rule, be greatly helped by diastase alone. If this does not work well alone, it will do better when combined with salol, or some similar antiseptic. The more I have used these remedies the better I have been pleased with them.

---

[1] Since this paper was written, I have been informed by Mr. F. A. Thompson, a skilful chemist, who has given close attention to this subject and performed a number of elaborate experiments with diastase and other digestive ferments, that he has found that Taka-diastase does undoubtedly not only disintegrate albumens but produces albumoses and peptones as well. This is an important and interesting discovery, and perhaps confirms the work of the German chemist Bezanes, who found that in producing diastase from malt, a by-product, which he named peptase, was formed, which acts on albumen. It is therefore evident that as there is formed in grain a product to change the albumen of the grain as well as the starch-converting ferment, Eurotium has a ferment similar to peptase for converting vegetable albumen for its nourishment. The peptase produced in malting is extremely slow in its action, due perhaps to its being interfered with by the thick gummy malt products.

[1] See Dr. Chapin's remarks in the discussion following.

I recall an interesting case of vomiting during pregnancy. The patient suffered from inability to digest both proteids and starches, but particularly the latter. She suffered very greatly from the resulting distension, but this was overcome by the administration of Taka-diastase. After awhile the stomach rebelled, but then, by washing the stomach, it became possible to return to proteids. One or two patients have come to me from a distance suffering from an aggravated form of starch indigestion, and these have done exceedingly well upon diastase. One of them improved with diastase alone; the other did better when it was combined with salol. Our trouble with the digestive ferments is that we do not pay sufficient attention to the different forms of indigestion, usually preferring to depend chiefly upon a routine dose of rhubarb and soda.

Dr. William A. Walker: I have had the most satisfaction from the use of the Taka-diastase. One advantage is that it is tasteless. I prefer to give it in capsules, because if administered in the dry form the patient usually complains of a dryness of the throat.

The question is often asked: What is the advantage of giving the diastase? It has been argued, principally on theoretical grounds, that the giving of an artificial digestive agent cannot produce a cure, but that it simply does a certain amount of work which the stomach should perform. I think Dr. Fothergill spoke of this practice as "pauperizing the stomach." This may be true in long-standing cases, but it certainly does not apply to the more acute cases. Most of its good effect is produced by supplementing the digestive ferments of the stomach. I have found, in certain cases, that in washing out the stomach a portion of the food ingested the previous day was present. I have then given the diastase, and have found, on subsequent washings, that a good portion of the food had been digested. The cure is effected, I suppose, in this way. Most of the trouble in dyspeptics is probably due to the leaving over of some undigested food from one meal to another. The diastase prevents this.

Dr. George Tucker Harrison: This is a subject in which I have taken a great interest for some time. Like most clinical observers, I often meet with these cases of indigestion, which in former times we erroneously looked upon as due to proteid instead of to amylaceous indigestion. I therefore hail with pleasure, as a great addition to our therapeutical resources, this new diastase—a substance which certainly appears to be worthy of extended and careful trial.

Since my attention was called to this new diastase, I have used it considerably, and have been much gratified with the results of my observations. One case comes to my mind. A lady of fifty-five years had taxed my therapeutic resources to the utmost. I had used, among other things, a preparation of nux vomica, pancreatin, and fel bovis inspissatum. This utterly failed. I began then the use of Taka-diastase, and the result was truly brilliant. The woman suffered from the usual symptoms of intestinal indigestion; flatulence, colicky pains after eating, mental depression, insomnia, etc. In other cases I have met with equally good success.

Dr. Henry Dwight Chapin: There are two well-known methods of acting on the casein of cow's milk for infants, *viz.*: (1) the mechanical, and (2) the physiological. The mechanical method consists in adding some diluent, such as barley water, or the old "flour ball." I think that, on the whole, we get better results by mechanical means than by peptonizing the milk. When the method of peptonizing milk was first brought out, most of us thought that the problem of infant feeding had been largely solved. I tried the method with much enthusiasm, yet I found that the simple peptonizing of milk, did not, on the whole, give very good results. In some difficult cases it certainly does succeed, but this has not been the rule in my experience.

This has led me to go back to the old method of attenuating the milk by the addition of cereals. We all know that young infants cannot digest much starch, although they can digest some by means of the mouth secretions and the secretion of the intestinal mucous membrane. I made a series of experiments at the laboratory and at the bedside regarding the action of diastase on barley. I think we succeeded in this way in getting the good effect of the attenuating qualities of the barley, and at the same time, in reducing to a minimum the bad effects of the starch. Clinically, this method gives good results in very many cases. The process is not a difficult one, and this, in itself, is a recommendation for the method, for in infant feeding it is highly important that the rules for the preparation of the food shall not be complex. Even skilled nurses often make mistakes in the process of peptonizing milk.

Dr. Morris Manges: My own experience strongly corroborates that of others as to the value of diastase in infant feeding. How it acts, I do not know, but I know that it does act. With children who do not thrive on breast milk, or substitutes for it, I can say that the addition of Taka-diastase has given me uniformly good results. This is a simple clinical fact.

I believe the use of preparations of diastase has been of service in one way particularly, *i. e.*, in calling our attention to the importance of the saliva in digestion. We had almost lost sight of its value, notwithstanding the fact that it is secreted in such large quantities. We must admit that so far as experimental work has added to our knowledge, we are still much in the dark regarding this important fluid. Just to what substance in the saliva the action on the starch is due, aside from the ptyalin, we do not know. Certainly it is not the ptyalin alone. The experiments of Jawein of Vienna, and of others, have shown that the ptyalin was lessened in certain acute infectious diseases, diabetes, and in renal and cardiac diseases; but strange to say, it was not at all lessened in tuberculosis. On the other hand, experiments by Friedenwald have shown that saliva can be boiled and the ptyalin thus killed, and yet the saliva will have a beneficial action in promoting starch digestion. It is evident, therefore, that other constituents besides ptyalin are at work.

Now, by giving Taka-diastase, can we really replace the saliva? That a ferment is, after all, not the original digestive fluid is a point which is very often lost sight of. Every single digestive juice shows us that there is something more than the ferment which is active. Just what important *rôle* is played by the carbonates, and by the nascent oxygen in the mouth, is not yet known.

Dr. William Henry Porter: There is one idea which is very prevalent in connection with starch, and which I think is a very erroneous one; and that is, that starch is a fat-producing element *per se*. I do not believe the animal organism ever converted starch into fat. If what the chemists say is true, that statement is a correct one. They say that when you commence to split up the starch compounds in the animal organism, they tend to become less complex, and that synthesis does not occur in the animal organism. Therefore, I believe we must give up the idea that fat was ever made out of starch. The only reason for that belief was an experiment made many years ago, in which two pigs were taken from one litter, both pigs being of about the same weight. Pig No. 1 was cut up and a quantitative estimate made of the fat. Pig No. 2 was fed on starch, and nothing else for a week or ten days. It was then killed, and a quantitative analysis showed a little more fat than in Pig No. 1. Consequently, the statement has been handed down for years that starch is converted into fat. I believe that all the fat we get in the animal economy comes from the katabolic destruction of proteid bodies, and I think we have pretty good clinical evidence of that. Were we to cut off every bit of starch and use simply proteids, sugar, and fat, these people, in the absence of starch, will progressively increase in weight. This comes, I believe, from a better utilization of the proteid elements, and not of the starch and fats. I believe that the fats and the starches are simply heat producing elements. A proper adjustment of the starches and fats is necessary, and when we cut off the starches, I believe we must substitute a little alcohol to generate the heat in about the same proportion as would be generated if we used the starch. A certain number of grams of starch are capable, for instance, of producing a certain amount of heat. If we deprive the system of that amount of starch, we must get that equivalent of heat out of alcohol.

If we consider many of these numerous little points I think we can very satisfactorily manage these cases of indigestion. Personally, I do not like the terms "albuminous," or "amylaceous," or "fatty" indigestion. I think the difficulty is either a gastric one or an intestinal one, and, therefore, in my opinion, these are the only two kinds of indigestion that we should consider from a clinical standpoint. The sooner we come to this simple method of considering the subject, the quicker we shall arrive at a more rational basis of treatment.

Dr. Charles Henry Brown: We have heard to-night regarding the use of diastase in the feeding of infants. Practically, it aids in the digestion of amylaceous substances. I have used for years some form of diastase in the artificial feeding of infants, from birth until they are able to take food independently of the bottle, and I think it is a very great aid to us in the frequent but puzzling idiosyncrasies of infantile indigestion. The question Dr. Porter has raised as to whether starch alone makes fat or flesh is not one for the discussion—it is rather the chemistry of the action of diastase, which undoubtedly produces a certain amount of flesh. If we give pure alcohol, we do not see it; if we give malt, we do see it. People at the time of life when the heat-producing mechanism is most active, put on flesh. A certain force produces this flesh and a storing up of fats.

In Taka-diastase I think we have a better preparation for treating certain forms of indigestion in adults than any other. It is a powder, and the diastase is measurable. The addition of alcohol interferes seriously with the digestive action of diastase. All of us know that malts which contain a large quantity of alcohol often increase the distress of dyspeptics. There can be no question that Taka-diastase is a remedy which we can use either internally, or in pre-digesting food. We can also use it in aiding nutrition. Undoubtedly, the use of diastase increases nutrition, probably by stimulating the proteids and increasing heat-production by its chemical action on starch. I have found that delicate infants, when given Taka-diastase in proper quantities, will show the results of this stimulant action, as well as delicate adults. When given symtomatically, it relieves the distress experienced in the various forms of amylaceous dyspepsia. This seems to me to cover the whole subject, so far as it is at present known.

Dr. Grover C. Arnold: What are the maximum and minimum doses of Taka-diastase for adults and infants?

Dr. Fite: In experiments at the laboratory, it seemed that one grain converted 1500 grains of starch in three hours, 100 grains in ten minutes. After extended observation it was determined that 2½ grains, given during a meal, was an average dose for an adult. Some physicians have used five grains at a dose, but this has appeared to cause too rapid a conversion of the starch. It seems that the doses for infants are proportionately larger, *i.e.*, one grain for a child of two years.

Dr. John Blake White: I should like to speak with reference to the practical aspect of the subject. Theory is beautiful indeed, and is most fascinating, but actual results, and the practical side are, after all, more important. I cannot discuss chemistry with Dr. Porter, but I can speak of the results obtained in practice. These substances certainly do produce fat. Whether this can occur from the chemist's standpoint, or not, I cannot say, but the fact remains.

I desire to add my testimony to the value of assisting faulty digestion by the means that have been discussed here this evening. My experience with Taka-diastase, and other digestive ferments, tends to confirm the position taken by the essayist. I have always looked upon my cases from a purely practical point of view, endeavoring to ascertain what was really at fault, and then remedying this. I endeavor to regulate the diet. In cases where the indigestion appears to be due to the defective digestion of starchy matter, we can resort with advantage to the use of preparations of diastase. The weight of authority certainly favors such a view.

CLINICAL MEMORANDA.

A CASE OF AGALACTIA.

By J. IVES EDGERTON, M.D.,
OF NEW YORK;
HOUSE-PHYSICIAN TO THE NURSERY AND CHILD'S HOSPITAL.

Agalactia, or the complete absence of milk secretion in the puerperal woman, is very unusual. Norris, in the "American Text-Book of Obstetrics," says: "So rare is this affection that its existence has frequently been doubted. Usually there is only a deficiency, which may occur at the beginning, and continue through the whole period of lactation, or, more commonly, the secretion, at first sufficient, gradually diminishes in amount, or, from some intercurrent affection, suddenly disappears. The secretion of an abnormally small amount of milk may be due to an anomaly in the formation of the mammary glands, either congenital or acquired from faulty clothing compressing the glands. It is also observed in the very feeble, in women of advanced age, after premature births or still-births, or in women who carry an excessive amount of adipose tissue. Temporary diminution or disappearance of the milk occurs when there is high fever, and when inflammation of the breast is present."

The following case occurred in the service of Dr. J. J. Hull, through whose courtesy I am enabled to report it:

Mrs. E. W., aged twenty-five, born in England; primipara. Was admitted to the hospital October 26, 1896. The history she gave was as follows: Before puberty she had had whooping-cough, scarlet fever and diphtheria. Five years ago she had pneumonia; never any other sickness, except occasional attacks of muscular rheumatism. She first menstruated at the age of twelve years, her periods recurring regularly every four weeks, and lasting for six days; flow was considerable and painful for the first two days. Her last menstruation was from January 14 to 19, 1896, and she "felt life" in July. She had some vomiting at irregular periods throughout her pregnancy, but stated that she had been subject to bilious attack since childhood. She had never had a miscarriage. During February she had taken frequent doses of pennyroyal, as also some other abortifacient, but with no other effect than the production of a profuse diarrhea. Since then she had taken no medicine. After the first month of pregnancy she noticed that her breasts were slightly enlarged, and this enlargement has persisted, but at no time had she noticed the presence of milk.

On admission she said she had had labor pains for three days. The internal os admitted one finger. The next day she had a normal delivery. Her breasts were examined carefully; they were normal in size and appearance, with well-formed nipples, and seemed to contain the usual amount of glandular tissue, but not a drop of colostrum could be obtained, either by massage or by the use of a breast-pump. The day after delivery a strong baby was given her to nurse, but no milk showed at the nipples. For sixteen days after confinement, with the exception of the sixth, seventh, and eighth days, this was tried, but with the same result. The breast-pump and massage were also tried on different occasions, but absolutely no milk could be obtained. The breasts never showed any engorgement. Uterine involution and the puerperium were normal, the patient being up on the tenth day. She had no rise of temperature above normal during this period. Her baby was a female, weighing 2825 gms., and has done well on another woman's milk. Although the child was below weight, its appearance and the menstrual history of the mother would not lead one to think it premature. The patient herself is about five feet two inches in height and weighs about 120 pounds. Her family history is of interest. Her mother is living and in good health, having borne nine children, three of whom are now living; four died at about five years of age, one at eight, and one at twelve months. The patient is the eighth child, and says her mother has often told her that in none of these puerperia had she any milk, although the breasts were natural in appearance. The patient has one married sister, who at twenty-five years gave birth to a full-term child, and she, likewise, never had a drop of milk for her baby.

In this connection, what Winckel says is of interest: "Harlan, Reil, Pitschaft, Hohnbaum, and Berndt, Jr., assure us that they have repeatedly observed the complete absence of the formation of milk in lying-in women, and have found this in several successive childbeds in the same woman. . . . This anomaly may be inherited by the daughter from the mother." It will be observed that in this case none of the usual causes was present. The woman was strong and healthy, but not obese, and only twenty-five years old. She gave birth to a full-term and living child. She had no rise of temperature, and no intercurrent disease during her puerperium. She now has been under observation for over two months and no milk has appeared.

A CASE OF CARCINOMA AND SARCOMA OF THE NOSE.

By D. MILTON GREENE, M.D.,
OF GRAND RAPIDS, MICH.

GRYNFELDT says that notwithstanding the fact that the nasal mucous membrane is the most frequent seat of inflammation, malignant disease in this locality is extremely rare. Cornil and Ranvier have maintained that there is no well authenticated case of primary carcinoma of the nose. About forty such cases have been reported, but of these, only a few of the growths were subjected to microscopic examination. The diagnosis in all the other cases was made from the gross appearance of the lesion and the clinical history. Sarcoma of the nasal passage is almost as rare as carcinoma. So far as I have been able to learn, there is no recorded case of a mixed growth of carcinoma and sarcoma of the nose; indeed, it has been stated by some pathologists that sarcoma and carcinoma very rarely, if ever, are found together anywhere in the body, while others claim that they do occur together, but that the cases are extremely rare.

Mrs. K., aged thirty-two, referred to me by Dr. C. M. Kelley, presented the following history: She had had a catarrhal condition of the nasal mucous membrane for years, accompanied by an offensive discharge, for which she had been treated. The symptoms had subsided when I saw her, and she had been quite free from the trouble for some time. During the previous eight months she had had nasal stenosis, especially on the right side, together with pain and a slight discharge. Since three weeks previously the pain had increased, becoming more constant, and changing in location from the bridge of the nose and forehead, where it had formerly been, to the right eye, cheek, temple, and ear. She had had epistaxis frequently.

Upon examination, I could discover no external signs of disease, no exophthalmos or displacement of the eyes, and could not make out the presence of a growth in the orbit. The left nasal cavity was quite free, as were the post-nasal space and vault of the pharynx. The hard and soft palate were of normal color and free from inflammation. In the right nasal cavity I found the middle and lower turbinated bodies swollen, hard, and infiltrated, and they did not contract under the local application of a six-per-cent solution of cocain. The middle turbinated body was the seat of an ulcer which, macroscopically, looked like an epithelioma, having the same appearance presented by an epithelioma of the lip. Protruding from between the middle and lower turbinated bodies, in the region of the *ostia maxileare et ethmoidea*, there was a growth as large as half of a small almond. The ulcerated turbinated covering bled freely when touched with a probe, but the growth did not bleed so readily. It looked like a vascular polyp. It was grasped with a pair of small forceps, but being friable, it broke down and left a large bleeding base. I had been impressed by the history of the case, notably that of the pain and bleeding, and had thought that the disease was malignant. Of this I was more convinced after attempting the removal of the growth. I then inquired into the family history, and found that her father had died of cancer of the stomach.

The patient went to her home. I informed Dr. Kelley and the patient's husband of what I had found, and said that I believed the disease to be malignant. I saw her at her home twice subsequently, having been called on account of the pain and continued bleeding. Several physicians were consulted at about that time and gave various opinions, mostly to the effect that the pain was caused by the removal of the growth. Nearly three months later, as she had been steadily growing worse, I was called in again, and found that the growth in the nose had returned and was larger than when I first saw her. There was exophthalmos of the right eye, the organ being displaced markedly to the temporal side of the orbit. A growth could then be felt in the orbit in the region of the ethmoid cells. It was quite evident that the growth did not originate in the antrum of Highmore, as in such a case the eye would have been displaced upward. An operation was requested, and I consented to perform it, after telling them of the liability of the disease returning.

On January 27, 1896, I operated by making an incision one inch long at the lower border of the supra-orbital ridge, extending to the nasal bone, then carrying a second incision vertically from this point to the inner side of the lachrymal sac, thereby exposing the growth. Passing my finger into the orbit and using it for a guide, I passed a sharp curette through the nose and scraped away the growth, together with the middle turbinated body, the ethmoid cells, and a portion of the sphenoid bone, which had been softened by the disease. There was quite a sharp hemorrhage. Some shock followed the operation, but the patient soon rallied. The external wound healed quite promptly, except a very small hole. The temperature rose to 100° F. but once; the remainder of the time it was normal.

The patient was relieved of her pain for about one month, when the growth showed signs of returning. The pain, which before the operation had been severe and constant, returned with the return of the growth, and she begged for another operation, which I performed on February 28th. This time I operated entirely through the nose and scraped away the remaining turbinated bodies and a portion of the ethmoid, together with all of the diseased tissue within reach. The shock was extreme, and she came near dying on the table, but she finally recovered from the effects, and went on as she did after the first operation.

The disease promptly returned, and she died a month later. Before death she was delirious for three days, and became almost completely blind. The growth was examined by three pathologists—Dr. George Baert, Dr. J. B. Whinnery, and a member of an association of pathologists in Chicago, neither knowing what the other had found. Each and all found mixed-celled sarcoma and carcinoma. The autopsy, which included only the brain and interior of the skull, was conducted by Dr. Sharp. The brain was fairly healthy, the dura being somewhat inflamed. The right orbital plate of the frontal bone had been entirely absorbed, and the left orbital plate was softened. The immediate cause of death was not ascertained.

SPECIAL ARTICLE.

THE NEW YORK ACADEMY OF MEDICINE—CELEBRATION OF ITS SEMI-CENTENNIAL ANNIVERSARY.

THE fiftieth anniversary of the inauguration of the Academy of Medicine was celebrated January 29th by commemorative exercises held in Carnegie Hall and a social gathering in the reception rooms of the Academy. This jubilee year has awakened anew the recollections of the circumstances that led to the organization of this institution, and the early struggles that the founders underwent to place it upon an enduring basis. The objects of the Academy, as set forth in its preliminary announcement, were:

1. The cultivation of the science of medicine.
2. The advancement of the character and honor of the profession.
3. The elevation of the standard of medical education.
4. The promotion of the public health.

These objects have been steadily kept in mind, and have made the Academy a power for good in these several directions.

On the adjournment of the Society for the Relief of the Widows and Orphans of Medical Men, after its fourth annual dinner, on the 18th day of November, 1846, at Peteler's, a then famous down-town restaurant, such well-known physicians as John Stearns, John W. Francis, Valentine Mott, Isaac Wood, Alexander H. Stevens, Thomas Cock, James R. Manley, Joseph M. Smith, John P. Batchelder, Henry D. Bulkley, Willard Parker, and others, remained to discuss the condition of the profession in this city and to consider what could be done to elevate it.

The result of the discussion was an invitation to the profession to hold a general meeting at the hall of the Lyceum of Natural History on the following 12th of December.

A small hall in Wooster street, over a coal yard, was secured as a place of meeting, and there the Academy continued to meet until June, 1850, when it moved to the smaller hall of the New York University. Later on its meetings were held in the lower lecture room of the College of Physicians and Surgeons.

As far back as the date of the incorporation of the Academy, June 23, 1859, subscriptions were solicited for a building fund, but it was not until 1875 that a building was purchased. On the 20th of May, 1875, it for the first time held a meeting in its own home, No. 12 West Thirty-first street.

A building having been acquired, renewed efforts were made to obtain a library. Many of the members contributed books from their private libraries, and some gave their entire collections, but the first real impetus was given when Dr. Abram Du Bois, although not a member, contributed several thousand dollars for the purpose of building a library hall at the rear of the building.

Library Hall, as the new part of the building was called, was finished and occupied in the fall of 1879, and thereafter rapid strides were made toward the great library which is now the proud possession of the Academy. It is now contained in the new building on West Forty-third street, consists of about 50,000 volumes, and, with the exception of that of the Surgeon General of the Army at Washington, a National affair, is the largest medical library in the United States.

Within a few years after the Academy had purchased a home in West Thirty-first street it outgrew its quarters, and strenuous efforts were made to acquire a more commodious and better adapted building. The present home in West Forty-third street was the result. The building, with the land upon which it stands, cost $284,426.59. It was built with subscriptions, large donations, and the proceeds of the sale of the Thirty-first street house. It is free from debt. The Academy's property, as shown by the Treasurer's report of December 15, 1896, is worth $336,740.82. There are a number of lecture, prize, library, and other funds that have been given for specific purposes.

The corner stone of the present building was laid in 1889, and in 1891 the edifice was ready for occupancy. It is a six-story structure, 75 feet front, and 100 feet deep. Its façade is of a Scotch redstone that was imported for the building. Its interior is especially adapted for the purposes of the Academy, and its arrangement is excellent. The library has accommodations for 200,000 volumes.

Of those who helped to found the Academy in 1847, the following Fellows are still alive and connected with it: Drs. Thomas M. Markoe, Edwards Hall, Lewis A. Sayre, and S. S. Purple, of this city, and John T. Metcalf and William Young.

The following is a list of the Presidents: Drs. John Stearns, John W. Francis, Valentine Mott, Isaac Wood, Alexander H. Stevens, Thomas Cock, Joseph M. Smith, Willard Parker, John P. Batchelder, John Watson, James Anderson, Alfred C. Post, Henry D. Bulkley, Edmund R. Peaslee, Austin Flint, Samuel S. Purple, Fordyce Barker, Abraham Jacobi, Alfred L. Loomis, D. B. St. J. Roosa, Joseph D. Bryant, and Edward G. Janeway.

The celebration proved a most enjoyable affair in every particular. The audience was composed of a large number of the most distinguished physicians of the city and State; of men prominent in the other professions; of well-known scientists and public men, and of representatives of the highest social circles of New York. The exercises consisted of an invocation by Bishop Potter, remarks by Dr. Joseph D. Bryant, the retiring President of the Academy, some reminiscences by Drs. S. S. Purple and Lewis A. Sayre, and an oration by Dr. Abraham Jacobi. This led up to the occasion of the evening, which was an address by President Cleveland.

Dr. Jacobi reviewed the work accomplished by the Academy, and the great progress of scientific medicine during the last fifty years. He referred to animal experimentation, and said that although many persons considered this branch of study cruel and unnecessary, there were many diseases which could be studied only by animal experimentation. The progress of medical science, he predicted, will be very great during the next fifty years. Its methods of investigation will not be changed, because they are now based on natural science, and medicine is now a part of natural science; but it will develop and progress, and become more and more a part of the education and culture of the people. Its ideal is the improvement of man, physically and intellectually.

PRESIDENT CLEVELAND'S ADDRESS.

"I have anticipated the share assigned to me on this occasion with considerable trepidation for various reasons. I have been chiefly disturbed because of my inability to discover sufficient ground for my right to join those who celebrate the semi-centennial of a medical association. I do not forget, however, that seven years ago I was accorded the privilege of participating in the exercises when the corner stone was laid of the building which is now the home of the organization which to-night celebrates its half century of useful and honorable existence.

"But this incident, which aroused an interest still undiminished in the Academy of Medicine, hardly entitles me to a share in the felicitations of those who have since borne the heat and burden of its work, while I have enjoyed the ease and happy surroundings of public station.

"Confessing, therefore, that I have no right to even standing room within the inner circle of the profession, I I have boldly and without the least authority determined to speak to you as a representative of the vast army of patients and laymen.

"At the outset I desire to remind you that you owe us much. Though largely in the majority and with plenty of members to spare, those who are well conducted among us do not vex you with hurtful competition. Instead of making life hard for you by an observance of the laws of health, we assist you by indulging in all sorts of irregularities. We are obedient and submissive to your commands—that is, when we are sick—and we sometimes pay your bills even after a recovery to health, which we are always certain would have resulted without your interference.

"We begin by conceding most heartily, and without the least reservation, the learning and skill of those now constituting the medical profession, and the wonderful advance that has been made through their untiring labors and investigations, in the alleviation of human suffering and the saving of human life.

"It may be that this seems to you an acknowledgment so much your due as to be hardly worth making. You should, however, value it, because it is sincerely made by those who were not born yesterday, but who hold in lasting and tender memory the ministrations of the village doctor of fifty years ago, and are now the living monuments of his faithful care. He, too, alleviated suffering and saved human life. We know that it was not given to him to see the bright lights that now mark the path of medicine and surgery, but you cannot convince us that he groped entirely in the dark.

"We remember without abhorrence his ever-ready lancet and the scars of his blood-letting found in every household. We endure with complacency the recollection of his awful medicine case, containing bottles, powders, and pills, which, whatever might be thought of them now, seemed then to be sufficient for all emergencies—to say nothing of the tooth-pulling tools and other shiver-breeding instruments sometimes exposed to view. If he was ignorant of many of the remedies and appliances now in use, he, in a large measure, supplied the deficiency by hard-headed judgment, well-observed experience, and careful nursing. Besides, it was in his favor that he did not have to bother his head with many of the newly invented and refined diseases that afflict mankind to-day. He had no alloted hours for his patients, but was always on duty, and we knew the sound of his gig as it rattled past in the night.

"Your ways are better than his; but we desire you to regard this admission as all the more valuable because it is carved out of our loyalty to our old village doctor, who brought us through the diseases of childhood without relapse, who saved from death our parents and our brothers and our sisters in many a hard combat with illness, and who, when vanquished and forced to surrender, was present in the last scene to close the eyes of his dying patient and sympathize with those who wept.

"I hasten to say that we do not for a moment suppose that advancement in the science of medicine and surgery has smothered the faithfulness and tender consideration which characterized the practitioner of former days. If we seek charitable service to the sick and suffering, a noble appreciation of obligation to humanity and self-abnegation in the discharge of professional duty, we must look for them among our physicians and surgeons of to-day.

"If we have now arrived at an understanding, you are, I hope, prepared for a suggestion quite in keeping with the extremely moderate and reasonable disposition that characterizes the patient and layman. You have invaded our benighted contentment and led us out into broad fields of scientific discovery. This has inspired us with a new-born spirit of wisdom and criticism which demands that new and larger fields be opened to our complacent gaze. You have penetrated the places where the germs of disease are hidden. We are quite certain that you should be required to destroy the origin of disease and ultimately to usher in the day when the only escape from the world will be through a passageway marked 'Old Age Exit.' If this has the appearance of exacting too much, or if business considerations present obstacles to its accomplishment, I think we ought, perhaps, to reduce our claims, or at least give our doctors time to find other employment.

In the meantime, those of us who are conservative must be allowed to hope that further investigation will continue to point the way to the prevention of disease. For this investigation we must still rely upon the efforts of those who have already done so much in that direction, encouraged and stimulated by such effective organizations as the Academy of Medicine. We are sure that this work, having arrested the attention of the world's brotherhood of medical science, will not be neglected; nor need we fear that America's contribution to splendid results will be deficient.

In some instances, however, investigation has performed its part, and only effective action in other quarters is necessary to supply needed remedies. In such cases, of course, you were absolved from all responsibility in your professional character by exhibiting dangers and warning against them. Thus certain diseases which you deem contagious yet remain imperfectly isolated. You have demonstrated the peril to health of unwholesome water and noxious surroundings, and yet much remains to be done by way of protecting our people against these dangers.

"You have established a code of ethics which condemns charlatanism in all its forms; and yet ignorant pretenders roam over the land offering to perform miracles, or are located in our towns and cities, preying upon the weakness of the sick and afflicted, while men and women are allowed to die without medical attendance, deluded with the hope that faith will save them in their last extremity. Within the limits of your professional power and influence you seek to restrain any approach to criminal malpractice; yet newspapers disgustingly, yet covertly, advertise the way to such crimes, and startle their readers with sensational tales of death and misery to which they are directly accessory.

"I need not suggest that such evils are allowed to exist by reason of the insufficiency of our laws or a laxity in their execution. I have intimated that for this condition you are not responsible in a professional sense, but are you sure that as citizens you are doing all in your power to remedy the situation?

"The village doctor was not only our physician, but he was a man of influence in all neighborhood affairs. In every matter that concerned the good of the community he was at the front. He was president of the village or represented his town in the county board of supervisors, and if he was ever late in visiting a patient it was because he lingered at the post-office to discuss the political situation. Thus he joined with the performance of professional duty a discharge of the obligations of citizenship.

"We cannot but think that the discoveries and improvements in the medical practice which we now enjoy are dearly bought if the members of the profession in their onward march have left behind them their sense of civic obligation and their interest in the general public welfare. We cannot accuse you of utter neglect of your duty to the country; and yet we cannot keep out of mind the suspicion that if your professional work in exposing evils were more thoroughly supplemented by labor in the field of citizenship, these evils would be more speedily corrected.

"If laws are needed to abolish abuses which your professional investigations have unearthed, your fraternity should not be strangers to the agencies which make the laws. If enactments already in force are neglected or badly executed, you should not forget that it is your privilege and duty to insist upon their vigorous and honest enforcement. Let me also remind you of the application to your case of the truth embodied in the homely injunction: 'If you want a job well done do it yourself.' If members of your profession were oftener found in our National and State legislative assemblies, ready to advocate the reformatory measures you have demonstrated to be necessary, and to defend your brotherhood against flippant and sneering charges of impracticability, the prospect of your bestowal upon your fellow-men of the ripened results of your professional labor would be brighter and nearer.

"While thus suggesting the need of your influence in legislative circles for the accomplishment of reforms related to your profession, you will, I hope, permit me in conclusion to enjoin upon you the duty of an active and general interest and participation in public affairs for the promotion of your country's good in all its phases. Our Government was founded in the faith and anticipation that those who loved it most and were best able to hold it steady would be at its helm. Without this it will surely go astray. Never did patient need your medical treatment more than the body politic now needs the watchful care of your patriotic and disinterested citizenship.

"No object of personal ambition and no activity of professional life should be permitted to withhold from our Government the tithe of devotion and service due from its thoughtful, intelligent, and educated citizens. The reward of a willing recognition of our obligation to watch and protect our free institutions and preserve them from weakness and decay, will surely come when a just government, supported by the patriotism of a loving people, shall bestow with equal hand upon us and all our countrymen the blessings of national peace, contentment, and happiness."

The large audience then repaired to the Academy of Medicine, where President Cleveland held an informal reception.

MEDICAL PROGRESS.

Large Vesical Calculus in a Boy Twelve Years Old.—VERHOOGEN (*La Policlinique*, 1896, No. 13, p. 655) has reported the case of a boy, twelve years old, who had suffered for six years with intense vesical pain, attended by an incessant desire to urinate. During the paroxysms of pain there was violent vesical and rectal tenesmus, and the small amount of urine voided had a strongly ammoniacal odor. The frequent rectal tenesmus and the repeated efforts at defecation had resulted in a considerable prolapse of the rectum. There had never been hematuria. The diagnosis of vesical calculus had long been made, but an attempt at removal by the perineal route had proved unsuccessful. By palpation through the rectum and the abdominal wall the stone appeared to be as large as a mandarin, and a process as large as a nut projected into the urethra. The size of the stone, as related to the capacity of the bladder, seemed to contraindicate lithotrity in favor of suprapubic lithotomy. The bladder being distended with about two ounces of sterilized water, and the patient placed in the Trendelenburg posture, a median longitudinal incision about two inches long was made in the abdomen above the pubes, and, after detachment of the peritoneal layer, the bladder was opened and the calculus exposed. The stone, whose peripheral layers consisted of phosphates, was very friable, and a good deal was first removed little by little. After some difficulty the calculus, which was adherent to the mucous membrane, was extracted, and the wound closed. The further progress of the case was uneventful. The interior of the stone contained three spherical nuclei of uric acid, each about the size of a cherry. Below it presented a pyriform prolongation nearly an inch long and an inch in diameter at the base. Its anterior surface was marked by a deep furrow corresponding to the inferior border of the pubic arch.

Pyemia in the Sequence of Acute Inflammation of the Middle Ear Following Diphtheria.—RIMINI (*Berliner Klinische Wochenschrift*, 1896, No. 27, p. 609) has reported the case of a child, 3½ years old, coming under observation on the sixth day of a mild attack of diphtheria. The symptoms disappeared in the course of three days, following an injection of the antitoxin, and convalescence appeared to have set in. Ten days after the injection, however, the temperature again rose, and a scarlatinoid eruption made its appearance, especially on the lower extremities. Two days later the temperature again suddenly increased, and on the following day there was complaint of pain in the right and subsequently also in the left ear, which was relieved by the occurrence of a copious discharge. In the further progress of the case several chills occurred, and the left knee-joint and the left forearm became swollen and painful. The pupils were dilated and sluggish in reaction, and the eyes deviated toward the left. Finally, coma set in and terminated in death. Upon *post-mortem* examination, the lower lobe of each lung presented evidences of bronchiolitis, but the larynx and trachea were free. The heart was small and firm. The liver was enlarged and in a state of fatty degeneration; the spleen also was enlarged. The mesenteric glands were tumid, and the kidneys swollen, anemic and fatty. The left knee-joint contained a considerable amount of turbid, purulent, grayish-brown exudate, and the connective tissue of the left forearm was the seat of serous infiltration. The brain was slightly edematous, but free from other alteration. Careful examination of the temporal bones disclosed the presence of dark, fluid blood in the transverse, superior petrosal and inferior petrosal sinuses. The external auditory canal, the middle ear and the antrum on each side were filled with thick, cheesy pus. The left tympanic membrane was entirely destroyed; the right presented a small perforation. Microscopic examination of the pus showed the presence of a large number of cocci only.

Splenic Leukemia in a Child Eight Years Old.—CHARON and GRATIA (*Bull. des Séances de la Soc. Roy. des Sc. Méd. et Nat. de Bruxelles*, 1896, No. 7, p. 63) have reported the case of a girl, eight years old, who came under observation with an abdominal tumor of six years' standing, mainly with a view to operation. Examination, however, disclosed the enlargement to be due to an hypertrophied spleen; and the liver also was increased in size. The subcutaneous veins of the abdominal wall were dilated, but there was no evidnece of any noteworthy ascitic effusion. A study of the blood disclosed the proportion of colorless to red corpuscles to be as one to five. The temperature was a little above the normal. The administration of an arsenical water was begun, but had to be abandoned on account of the resulting diarrhea. At a second examination of the blood the number of red corpuscles per millimeter was found to be 880,000, the number of colorless corpuscles 305,000 and the hemoglobin-estimation 39 per cent. Many of the red corpuscles were of increased size, a small number were nucleated, and poikilocytosis was marked. The colorless corpuscles consisted of small lymphocytes, multinuclear leukocytes or leukocytes with polymorphous nuclei, and large mononuclear leukocytes. Death took place with symptoms of dyspnea. Upon *post-mortem* examination the lower lobes of both lungs were found atelectatic. The spleen weighed 38½ ounces and presented evidences of white infarction; its capsule was thickened in places, its parenchyma pale and dense. Microscopic examination disclosed the existence of a uniform hyperplasia of the reticular structure. The liver weighed 63¾ ounces; its surface was smooth, its parenchyma pale and firm.

The parenchyma was remarkable for the enormous development of its vascular system, particularly the intralobular veins, which were filled with leukocytes. The hepatic cells were distorted and compressed. The lymphatic glands presented little abnormality, those of the mesentery containing large cells, with nuclei, resembling giant-cells.

Extra-Genital Infection with Gonorrhea.—AQUILA (*Monatshefte für Praktische Dermatologie*, 1896, B. xxiii, No. 1, p. 16) describes an unusual method of infection with gonorrhea, of which he was himself the victim, while acting as assistant in a large service for the treatment of cutaneous and venereal diseases. It was the custom to treat the cases of urethritis with injections of a three per cent. solution of silver nitrate, and to study bacteriologically the urethral secretions every third or fourth day, care always being taken to wash the hands afterward with soap and then immerse them in an antiseptic solution. The development of an eczema of the hands led to a temporary relaxation of these precautions, and in a short time a sense of burning was noticed on the preputial surface of the glans penis and at the extremity of the urethra. The irritation gradually increased, and in a little while a drop of pus made its appearance, examination of which disclosed the presence of gonococci. A typical attack of gonorrhea now developed and pursued the ordinary course. The infection is believed to have been incurred either through bathing in a tub used by infected patients, or directly from the undisinfected fingers used in making cover-slip preparations of urethral secretions.

THERAPEUTIC NOTES.

Injections of Carbolic Acid into the Parenchyma of the Tonsils. Acting upon the theory that recurrent tonsillitis is set up in most cases by retained germs, which, under circumstances unfavorable for the patient, rapidly develop and cause new inflammation, KRAMER (*Centralbl. für Chir.*, No. 47, 1896) has for some years been using parenchymatous injections of carbolic acid in order to destroy the retained bacteria. The patients so treated were those who, for a considerable period of time, had suffered from attacks of acute inflammation of the tonsils, occurring at intervals varying from two months to one year. There was no especial reason in the previous treatment of these patients why the trouble should recur. The cases in which abscesses had formed were treated by sufficient drainage and frequent gargling and irrigation with antiseptic fluids. Besides, in many cases, portions of the tonsils had been removed or the organs had been scarified with the cautery, carious back teeth had been extracted, etc.

The treatment was not begun until some weeks after the recurrent attack had subsided. It consisted in the injection of carbolic acid 1:40 every two or three days until four to six injections had been made. The sterilized needle of an ordinary syringe was introduced to a depth of one centimeter into the anterior pillar of the fauces, after this area had been cocainized, and if no blood escaped the carbolic solution was injected a drop at a time, the point of the needle being pushed in several directions, until ½ c.cm. (♏ xv) had been injected. At the subsequent injections another site was selected. The local reaction was slight. There was some discomfort in swallowing, the following day, but no general symptoms were excited.

A single case would not prove anything, but Kramer reports fifteen patients who have already passed two and a half years without recurrence of their previous trouble, and in numerous other instances two years or less have gone by without relapse, so that the author feels confident that the freedom from recurrence is to be set down to the influence of the injections.

Advantages and Disadvantages of Eucain in the Surgical Treatment of the Eye.—WUSTEFELD (*Münch. Med. Woch.* December 22, 1896,) used a 5 per cent. watery solution of eucain in twenty operations upon the eye. In every instance the patients complained of the sharp burning, which lasted a considerable time and produced dilatation of the vessels of the sclera. The anesthesia, however, was satisfactory, closely resembling in its beginning and its continuance that of cocain. In almost every case there was a difference in the pupils and paralysis of accommodation. The former was evident in fifteen minutes and the latter from ten to fifteen minutes later. Microscopic examinations of the eyes of rabbits showed in every case unmistakable evidence of the effects of the eucain. The epithelial cells were swollen, and in some places the upper layer was séparated from the under layer. After these findings it is scarcely probable that eucain will displace cocain in eye surgery.

Creosote in the Treatment of Children.—HOCK (*Wien. Med. Blätter*, December 3, 1896,) has had brilliant results from the use of creosote in treatment of children, not only in phthisis but in the sequelæ of whooping cough and the catarrh which so often follows measles. These two conditions, as is well known, furnish a favorable opportunity for tuberculous infection. The usual treatment with expectorants is too often without result. Most diseases of childhood are accompanied by disturbances of digestion, and these are the symptoms which are first relieved by the use of creosote. The appetite improves, the abdominal pain disappears, and weight increases. Later the pulmonary condition improves. It goes without saying that the creosote must be given in such a manner as not to upset the stomach, and large doses in a concentrated form are therefore to be avoided, the drug being given in small doses with meals. Pills, though cheap, are objectionable, especially for very young children. Hock tried in a number of instances to administer fluid creosote with tincture of gentian, but in almost every case the stomach refused the medicine after a few days. He was most successful with a 1 to 2 per cent. solution of creosote in codliver oil, to which one-twentieth of 1 per cent. of sugar was added. The dose of this mixture is from ½ a dram to ½ an ounce, three times daily, according to the age of the patient.

THE MEDICAL NEWS.

A WEEKLY JOURNAL
OF MEDICAL SCIENCE.

COMMUNICATIONS are invited from all parts of the world. Original articles contributed *exclusively* to THE MEDICAL NEWS will after publication be liberally paid for (accounts being rendered quarterly), or 250 reprints will be furnished in place of other remuneration. When necessary to elucidate the text, illustrations will be engraved from drawings or photographs furnished by the author. Manuscripts should be typewritten.

THE COMPULSORY NOTIFICATION ACT OF THE NEW YORK BOARD OF HEALTH.

JUST at present the medical profession of New York City is in a condition of hyperesthesia regarding its rights and prerogatives. It is quite possible that this may account for the somewhat irritable opposition that has manifested itself to the recent announcement of the Board of Health regarding the compulsory notification and isolation of cases of pulmonary tuberculosis. In these circumstances the disinterested judicial opinion of the *Boston Medical and Surgical Journal* may prove a gentle sedative to our overwrought indignation.

"We cannot but think that these provisions are in the line of future progress in the application of medical and sanitary science. Laws are only useful in so far as they can be enforced, and enforced with less loss and injury than is entailed by their absence. The useful and possible enforcement of the regulations under discussion will depend very greatly upon the tact, discretion, and good judgment of those entrusted with carrying them out. The working and the results of these regulations in New York will be watched everywhere with much interest.

"The question of diagnosis, of isolation, of treatment in the large sense, is decided to-day in the laboratory rather than at the bedside. There is a danger of being too ready with these new-found weapons, of expecting too much from them; but there is also the danger of rejecting them because they are new. The general practitioner may be a very desirable check upon the enthusiastic bacteriologist, but the practitioner, the hospital clinician, and the bacteriologist, should all coöperate cordially and heartily together, and carry the general public along with them by example as well as by precept. There is work for all, and distinction to be gained from good work by all, but there should be no room for jealousy and no time for hindrance."

As confirmative of the wisdom of the Board of Health in taking the position it has, the facts presented by Dr. Hance in a recent paper before the Academy of Medicine are of interest. The paper was entitled "A Further Study of Tubercular Dust," and was based upon experiments made by the reader at the request of Dr. Biggs. As a result of one of these experiments, three out of four guinea-pigs that had been inoculated with dust taken from a tenement-room in which a phthisical woman had lived and died, developed tuberculosis and died with well-marked lesions of the disease; while four guinea-pigs inoculated with dust taken from a room where a patient with tuberculosis lived, but who observed the regulations of the Board of Health, at the end of fifty-seven days, when the animals were killed, were apparently perfectly healthy.

THE ABUSE OF CHARITY.

WHILE the medical profession in all the larger cities of America is struggling with the great problem of dispensary and hospital abuses, similar problems are being encountered by our professional brethren across the water. We had occasion recently in our news column to refer to the fact that certain club or lodge doctors in the towns of Beckenham and Penge had been induced to combine and take a positive stand against a reduction in prices. In other words, the doctors threatened to strike in order to maintain the rate of fees. Unfortunately, the combine was defeated by the decision of the clubs to pool their interests and import a medical staff. Now it is reported that a wealthy resident of Beckenham has offered to build and furnish a dispensary at his own expense for the benefit of the club members.

A pitiful tale comes from the town of Sheerness in England, of a practitioner who was sued for non-payment of debt. He swore that he had been in practice in that town for five years; that he had a wife and one child; that his chief source of income was a club, the members of which he attended professionally at the munificent rate of one-halfpenny each, per week, from which he realized £1 17s. ($8.99), out of which he had to provide all drugs. His private practice yielded him an income of five shillings ($1.20) per week. Commenting upon this, the *Medical Press and Circular* says: "Can anyone propose that this miserable brother shall be prevented from earning the halfpenny a week upon which he and his family starve? Or that the people who expect to get capable advice and medicine for that sum shall be forcibly dispossessed of their hallucination?"

In Paris the same problem presents itself in a little different phase. Here we have an abuse of charity which has grown out of the "medical night service." This service is provided for by the city of Paris out of the public treasury, and the hours of duty are from 10 in the evening until 6 in the morning. The "*Medecins de nuit*," as they are called, volunteer their services. Any medical man who desires to join the corps is invited to inscribe his name in a book kept at the police station of his district. If any person falls suddenly ill in the night, a message is conveyed to the police and the police sergeant looks up the name of the medical man on the roll living nearest to the residence of the patient, and accompanies the practitioner to the house. The necessary attention having been given to the sick person, the sergeant pays the doctor a fee of 10 francs ($2.00). This sum is afterward charged to the prefecture of police, which authority takes steps to reimburse itself when the patient is in a position to refund the money, but when the patient has no means, the fee has to come out of the city treasury. The Municipal Council has stated that, while the medical night service is highly appreciated by the Parisian population, it is nevertheless a fact that, unfortunately for the city budget, the great majority of the persons who seek the aid of the service maintain that they should be attended gratuitously. This state of affairs has naturally led to the reorganization of the service upon a different basis. Under the new rules, 135 practitioners will be employed at an annual salary of £24 (about $120). This reduction of fees will place the staff in the position of receiving not more than 3 francs (60 cents) a visit. At this reduction the doctors are naturally indignant, and insist that if the new rules are permanently enforced they will be obliged to sever their connection with the department.

CONGENITAL SPASTIC RIGIDITY—LITTLE'S DISEASE.

IN 1862, the English surgeon and obstetrician, Little, communicated to the London Obstetrical Society the result of observations which he had made on a class of children born before full term, or at term, and often with the use of instruments. The defects which these children presented were principally somatic and to a slight degree psychic. The former consisted of diplegia of a spasmodic type, most strikingly manifest in the lower extremities, where it constituted a condition of paraplegic contracture, less evident in the upper extremities, although frequently sufficiently well-marked there to constitute a distinct impairment, and, least marked of all, in the cephalic extremity. The psychical defect consisted of lack of proper and timely development of the mental processes, which was very rarely of such a degree as to constitute a mild form of idiocy. This description has been perpetuated by almost every writer on the subject since that time. The symptom complex, although dating from birth, is not usually recognized until a number of months later—possibly at the time when a child endeavors to creep and to walk. Attention is then drawn to it by the inability to make either crawling or walking movements. In the beginning, the spastic, rigid condition may be quite well marked in the upper extremities; possibly, also in the cephalic extremity; but as the infant grows older, this condition tends to decrease, until, when it arrives at the age of beginning childhood, manifestation of the spasticity in the upper extremities is comparatively slight, and perhaps attracts no notice. The evolution of the disease-process in the lower extremities is very much more delayed, and oftentimes remains until the end of the patient's life, constituting a very distinct and striking deformity, of which the principal symptoms are rigidity, without particular loss of power, cross-legged progression when the patient essays to walk, increased myotatic irritability and loss of purposive movements. The condition is often known as congenital spastic rigidity, but very frequently, and particularly during the last few years, Little's name has been eponymically associated with it.

The pathogenesis and morbid anatomoy of Little's disease are still very obscure. Lately, van Gehuchten has turned his attention to the subject, and the result is that more illumination has been given it than at any time since its original recognition. His contributions have appeared in recent numbers of the *Journal de Neurologie*.

In discussing the clinical and etiological side of the disease, van Gehuchten points out that those authors who teach the occurrence of this condition in children born at full term with the aid of instruments are in error, at least in part. He believes that obstetricians are nearly in accord that the symptom complex of congenital spastic rigidity is commonest in children born prematurely; and it matters very little whether the birth be an easy or a difficult one. At this time of life the pyramidal tracts are almost wholly non-medullated and naturally, therefore, devoid of the ability to functionate. The first tracts to become medullated are those constituting the indirect motor pathway—the pathway through the pons-cerebellum—while the direct pathway—the cortico-spinal fibers—are very much delayed in acquisition of myelin sheaths, and perhaps may never develop them at all. In its downward growth during the latter years of infancy, the tract of the cortico-spinal fibers reaches first the upper and then the lower levels of the cord, those fibers destined for the lumbar and sacral portions requiring the longest time to reach their destination. In accordance with this, the rigidity and contracture disappear first in the face and head, then in the upper extremities, and remain longest and perhaps do not disappear at all in the lower extremities.

In short, therefore, this author contends that absence of the myelin sheaths of cortico-spinal fibers constituting the pyramidal tract is attended by the same clinical phenomena as degeneration of these fibers. In both conditions there is an absence of inhibitory action of these fibers upon the motor ganglion cells of the anterior horns, consequently the spasticity. If his claims are corroborated by other investigators, a very important step will have been taken for a satisfactory explanation of the pathogenesis of this condition, and possibly also for the prevention of its occurrence. If it be a developmental defect dependent upon premature birth, the prevention of the condition will simmer down to an obstetrical problem, to wit: How can delivery be delayed until the period of complete fruition?

These recent writings of van Gehuchten, which commend themselves to one because of the closeness of reasoning contained in them, especially reasoning from analogy on well-founded anatomical facts, will at least serve the purpose of calling the attention of the general practitioner, as well as of the neurologist, to the necessity of more accurate and trustworthy observation concerning the genesis and time of occurrence of the disease. At the same time they enlarge our perspective of the condition by furnishing us a different point of view from which to study it.

Joseph Collins, M.D.

ECHOES AND NEWS.

The New York Board of Health Censured.—Last week a coroner's jury brought in a verdict in which it censured the Board of Health for granting licenses to midwives without examinations. The case was that of the death of a woman after treatment by a midwife.

Officers of the Philadelphia Neurological Society.—At the January meeting of this Society the following officers were elected: President, Charles W. Burr; Vice-presidents, J. Hendrie Lloyd and J. Madison Taylor; Secretary, W. S. Spiller; Treasurer, Guy Hinsdale.

District Branch of the N. Y. State Medical Association.—The thirteenth annual meeting of the Fifth District Branch will be held in Brooklyn on Tuesday, May 25, 1897. All Fellows desiring to read papers will please notify E. H. Squibb, secretary, P. O. Box 760, Brooklyn.

Lord Lister to Visit America.—It is a great pleasure to be able to announce that Lord Lister is seriously considering a visit to New York during the approaching summer. No guest would be more honored and welcomed by the medical profession of America.

Deaths from Accidental Asphyxiation.—In Boston during the year 1896 there were twenty-four deaths from accidental gas-poisoning, a number greatly in excess of previous years and directly attributable to the water-gas now employed. This contains about forty per cent. carbonic oxid and a small proportion of naphtha gas. The former is odorless and consequently insidiously fatal. Professor Wood of Harvard Medical School suggests a larger admixture of petroleum gas, which has a most penetrating odor.

Control of Milk Supply in Minneapolis, Minn.—Minneapolis is one of the small number of cities in which the health authorities have undertaken to prevent the sale of milk from consumptive cows to the people under their jurisdiction, by requiring all dairy farmers who ship milk to the city to prove that their herds have been purified by means of the tuberculin test. One farmer rebelled against this requirement, and appealed to the courts, upon the ground that the city's Board of Health had no right to enforce such a regulation with respect to dairy herds kept outside of the city limits.

New York Polyclinic Medical School and Hospital.—The trustees of the Polyclinic have decided to erect a new building on the site of the old one. Funds have already been secured for this purpose and work is to be begun immediately. The building will be adapted in every possible way to the requirements of the institution, and the two upper floors will be devoted to hospital facilities. There is every reason to believe that in its new home the Polyclinic will enter upon a career even more successful than that which has characterized its existence to the present time.

The Use of Mice in Cleaning Bones.— The economic value of agencies formerly held in supreme contempt is being appreciated and utilized. Dr. Samuel H. Friend of Milwaukee, Wis., submits the following suggestion: After stripping the soft tissues as much as possible with a scalpel, place the bones either in a wooden box lined with tin, putting with them one or two dozen mice, or in a room overrun with the rodents. In a surprisingly short time the bones will be freed from all soft tissues. This method is especially adapted when it is desired to retain the spinal column and ribs intact. Tin caps over all cartilaginous ends will protect them.

Aryan Medical Etiquette and Superstitions.—"A Short History of Aryan Medical Science" has been written by a Hindu trained in Western science. From this it appears that the secret of long life is to look every morning at the reflection of your face in ghee. If you have no ghee, a looking-glass will do. "Looking eastward at meal-time" also conduces to longevity. A doctor who asks for his fee is unworthy of respect, but, on the other hand, if you do not pay him his due, your "stock of merits" will be transferred to him at your death, and his next incarnation will be just so much higher up the scale.

Funds for the New York Saturday and Sunday Association.—The association aims at interesting everybody in hospital work. The total of last year's collections was $22,190.76 from churches, and $58,919.45 from other sources. Bed patients numbering 30,700 were cared for. Of these, 23,271 were free. Medical aid was given to 250,000 free dispensary patients. The Executive Committee, in a statement, set forth that the hospital expenses of the past year were $1,323,238.15, with an income of $292,581.83 from funds invested; from paying patients, $299,996.79, and from the city, $66,047.91. The Association now embraces thirty-eight hospitals, and the collection is divided among them on the basis of free work performed by them during the year preceding on behalf of the poor.

New Medical Superintendent of the Manhattan State Hospital.—The State Civil Service Commission announces the appointment from the eligible list of Dr. Percy Bryant of Buffalo as Medical Superintendent of the Manhattan State Hospital, at a salary of $2,500 per year. Dr. Bryant is first assistant physician at the Buffalo State Hospital. He was born at Cedar Falls, Iowa, April 19, 1863, and at an early age began the study of medicine in Chicago. Later he was an interne in the Cooke County Hospital. From Chicago he went to New York, where he entered the College of Physicians and Surgeons, from which he was graduated in 1887. Two years later he went to Buffalo and entered the State Hospital as an interne. Afterward he was appointed third assistant, and finally first assistant. earning all of his promotions by merit.

A Flannel-shirt Club.—From this title, one would naturally fancy that a nautical club was meant, with members whose minds were on outings bent, but such is not the case. The matter is much more serious and worthy. It has been constantly observed that a repeated cause of suffering and often of fatal relapses among convalescent patients of the poorer class was due to the insufficient clothing with which they were discharged from the hospitals. In London a club has been formed whose members bind themselves to furnish enough flannel for a shirt, together with a small contribution in money, at least once a year. From this a shirt is made in the wards of the hospitals and each needy patient is provided with one when he receives his discharge. A more simple or practical charity has not been established.

Meeting of the American Medical Association.—The committee of arrangements for the fiftieth meeting of the American Medical Association, to be held in Philadelphia, June 1, 2, 3, and 4, 1897, desire to announce that in addition to the regular order of exercises during the meeting of the Association there will be for a week preceding and succeeding the Association meeting. special courses and clinics given in the various large teaching institutions of Philadelphia, without cost to visiting physicians. This course has been organized in response to a generally expressed wish that opportunities might be given to visiting physicians of taking clinical courses, for it is believed that many physicians from distant points would be glad to spend a week or two over and above the time occupied by the meeting in this manner. A schedule and roster describing the course in detail will be published shortly before the meeting. Further information may be obtained from Dr. Edward Martin, 415 S. Fifteenth street, Philadelphia, the Chairman of the Committee on Hospital Courses.

Officers of the New York State Board of Medical Examiners.—The following have been re-elected as officers of the State Board of Medical Examiners for 1897: President, William C. Wey, M.D., of Elmira; Secretary, M. J. Lewi, M.D., of New York City; Question Committee, George Ryerson Fowler, M.D., of Brooklyn, and M. J. Lewi, M.D., of New York. Since the existence of the present law and its active enforcement, extending over a period of five years, 2832 doctors of medicine have applied for admission to practice in this State. Under the old law all these would have been admitted unquestioned. The State Boards of Medical Examiners rejected 937 of those who applied, or 29 per cent. The State Medical Society has nominated the following for appointment to the three vacancies existing on the State Board of Medical Examiners: William W. Potter, M.D., Buffalo; William S. Ely, M.D., Rochester; A. Walter Suiter, M.D., Herkimer; Daniel Lewis, M.D., New York, and Ernst Stoddard, M.D., Rochester.

Control of Consumption.—General Emmons Clark, Secretary to the New York Health Department, in relation to the Health Board's plan to assume control of consumption cases, says: "The various critics of the Health Department and its plan to control consumption have, in my opinion, taken a false view of the proposition made by the Board. They seem to draw the conclusion that it was our intention to surround each case with a strict set of rules and to isolate patients and remove them from their homes. Nothing is further from our intention than this. The intention is to keep a close record of all cases, and insist that proper precautions shall be taken to give the patient proper attention and see that measures necessary to prevent infection from the patient are taken. We have no intention of interfering with practitioners in charge of cases, but in cases where persons are destitute and unable to receive proper attention we will see that they are cared for. In cases of death among this class of patients, measures will be taken to disinfect clothing and apartments, so that there will be no danger of a recurrence of the disease from any cause attributable to the last patient."

CORRESPONDENCE.

ACETANILID AS A SURGICAL DRESSING.

To the Editor of THE MEDICAL NEWS.

DEAR SIR: In your issue of August 15, 1896, an article by Dr. J. J. Walsh, on "The Inhibitory Action of Acetanilid on Bacterial Growth," strongly attracted my attention: and I was equally interested in Dr. Foote's study of Formalin-gelatin, published November 14. His paragraph on acetanilid, in which he speaks of its comfortable and satisfactory action for two or three days, and of its ultimate failure to check or prevent suppuration, fully agrees with my experience. From this experience I was led to seek some addition to acetanilid which would fully inhibit suppuration. I first tried boric acid, acetanilid, and carbolic acid; but the powders were not sufficiently absorptive, and the compound was too moist and pasty. After many trials I used this: Powdered acetanilid, 48 per cent.; powdered boric acid, 15 per cent.; powdered starch, finely sifted, 35 per cent.; carbolic acid, liquid, 2 per cent. This compound, though slightly moist and adhesive, has all the effect of a dry dressing; in fact, upon a wound it is or becomes perfectly dry. Its absolute comfort leaves nothing to be desired; under its use there is not from first to last the least discomfort except a momentary smarting on the first application, too trivial to be worth mentioning. The most exquisitely sensitive sore can in a few days be handled with impunity. There is no odor, even of the carbolic acid. It absolutely inhibits suppuration where it can reach the wound surface, and it checks and quickly abolishes suppuration if that be already present. The powder should be changed twice a day as long as there is a discharge to moisten it; soon, however, the wound becomes absolutely dry, and the powder may be left for days undisturbed, and will still be found as dry as when applied, unless there is a pocket from which pus may come. Cicatrization is rapid and satisfactory.

Obviously, this powder would be unsuitable for introduction into a cavity, unless it was intended that the cavity should granulate from the bottom; and in that case the possibility of easy removal of the masses formed by the pus soaking into the powder before the wound becomes dry, should be considered. On an accessible granulating surface, and upon a sutured wound, it is the nearest to a perfect dressing I have yet seen.

W. A. FALLAS, M.D.

HORTON, MICH.,
December 25, 1896.

A REQUEST TO THE MEDICAL PROFESSION.

To the Editor of THE MEDICAL NEWS.

DEAR SIR: During the last ten years I have appealed to physicians from time to time to send me the human embryos which fell into their hands, and have in this way procured some very valuable specimens. These specimens have been cut into sections, and are now being modeled and studied very carefully. Yet a number of important stages are still wanting, and I therefore ask through your columns that physicians send me any material which they may obtain.

The best method to preserve human ova is to place the unopened ovum, without handling, and as soon as possible, in strong alcohol. By this method the embryo within is well hardened for future microscopic study.

It is very injurious to wrap these delicate specimens in cotton before sending them by mail or express. A perfect method is to place the preserved specimen in a bottle filled completely with alcohol, thus imitating the condition of a *fetus in utero*. If there be no air or cotton in the bottle, it is almost impossible to injure the embryo by shaking it.

Very sincerely yours,
FRANKLIN P. MALL,
Professor of Anatomy.

JOHNS HOPKINS UNIVERSITY,
Baltimore, Md., January 23, 1897.

OUR PARIS LETTER.

[From our Special Correspondent.]

AN INSTANCE OF GROSS MISCARRIAGE OF JUSTICE DUE TO MEDICO-LEGAL SHORTCOMINGS—SECOND ANNUAL SESSION OF THE SOCIETY FOR THE ENCOURAGEMENT OF POPULATION IN FRANCE—THE DIAGNOSTIC VALUE OF THE TYPHOID SERUM REACTION IN TYPHOID FEVER.

PARIS, January 10, 1897.

DURING the past two months, France has had a very startling lesson as to the value of expert testimony. Now that all the facts are clearly before the public and the mistaken and much condemned medico-legal experts have had an opportunity to explain the terrible error that was made, we can realize how important for all countries is the lesson that it teaches.

The facts are about as follows: Some five years ago a woman of Rouen was condemned to penal servitude with hard labor for life for the suspected murder of her husband. Her character was bad, and she was addicted to drink. On the occasion of a previous illness of her husband she had been known to rejoice, and when he grew better she had been heard to say that he would be dead within the year, anyhow. There had been a series of quarrels between husband and wife shortly before his death.

The husband and a relative of the woman had become very sick after eating some food prepared by her. The sickness thus induced had proved fatal; in other words, there was a complete chain of circumstantial evidence implicating the wife in the crime, if crime there was. Legal measures were at once taken to bring the supposed criminal to justice. The stomach and intestines, the liver, kidneys, lungs, and brain, and a vial of blood, were sent under seal to medico-legal experts for examination. The only thing found by the experts was a series of deep erosions of the intestinal mucous membrane. These seemed to point to the action of an intensely irritant poison. No traces of the poison were found, but the experts declared that death had not resulted from natural causes but from the ingestion of some irritant poison. As examination of the various organs had proved negative in the search for traces of poison the blood was not examined chemically, but its appearance was noted as being dark in color, but not abnormal.

On the strength of this expert opinion the condemnation took place. In the statement of the case to the experts no mention was made of the fact that the house in which husband and wife lived, and in which he died, adjoined a limekiln; that, in fact, the wall between dwelling and kiln was of scarcely more than ordinary thickness. Time went on and other tenants of the same dwelling became sick and had to move. Finally, about a year ago, another death under suspicious circumstance took place, and public opinion, then thoroughly aroused, demanded an exhaustive investigation. Professor Brouardel and Drs. Ogier and Descoust of Paris, all well known as medico-legal experts, and the first a well known authority on legal medicine, were given charge of the investigation. They found that the last death was due to carbonic oxid poisoning, the gas being formed in large quantities during the incomplete process of combustion in the limekiln and diffused through the party wall into the adjoining living apartments. Asked to review the findings in the former supposed murder case, they declared that too to be undoubtedly a case of carbonic oxid poisoning, though with some anomalous features. For over six years the poor victim of incomplete investigation, legal misunderstanding, and unfortunate combinations of circumstances, had been suffering the severest penalty possible in France for a crime she had not committed. Her condemnation was revoked, her innocence formally declared, and she was awarded large compensatory damages, which might have benefited only her heirs but for the prejudice in France against capital punishment in the case of women.

The newspapers generally have very severely condemned the medico-legal experts in the case, but a dispassionate review of the circumstances shows the legal lights engaged in the case to be at least as blameworthy.

Before the explanatory statements of the experts, which appeared only a few days ago, it might have been thought that the error was merely a personal one due to overhasty judgment and the drawing of conclusions not justified by the facts in the case, but now it seems clear that the fault lies in the fact that owing to merely business relations, as it were, existing between court and experts, neither party was sufficiently informed as to important details, and the error resulted for which both must share the responsibility.

In sending the specimens to the experts the court said nothing of the presence of the limekiln near the scene of the supposed crime, and the attorney for the defense made no use of its possibilities, either in his general defense or his special plea. They do these things very differently with us, even when the clients are as poor as the defendant was in this case. The experts only gave an opinion that was justified by the *post-mortem* appearances as they had been interpreted by the authorities in legal medicine up to that time. Severe intestinal lesions of an erosive character had never been described as occurring in carbonic oxid poisoning. The dark color of the blood that comes with the presence of carbonic oxid instead of the rose-red tint, and its normal coagulation, instead of remaining fluid, removed the only clue that might have aroused suspicion of the true nature of the poison that had caused death.

The whole case is extremely interesting and points out the necessity, on the one hand, of giving detailed information to medico-legal experts of all the circumstances connected with the case, and, on the other hand, for the expert to frankly state the limitations of certainty in his conclusions where many of the findings are negative, even though suspicious lesions may exist.

Just before the close of the year the second annual session of the Society for the Encouragement of Population in France attracted a good deal of attention. Recent statistics show that as regards increase in population France is scarcely holding her own. In 1895 the excess of births over deaths, in the whole country, was scarcely more than 125,000. Most Frenchmen, I think, would not bother their heads about this were it not that in Germany during the same year the excess of births over deaths was more than 1,000,000. Public attention has been called to this very forcibly and now determined efforts are being made to have motives of patriotism if possible take the place of the other motives that are usually so effective, but which have lost their efficacy in France, for the propagation of the race.

Public interest took the shape of discussions in the newspapers of the causes that prevent the increase of population, and in these the doctors came in for their share of blame. Increase in the number of abortions, and the spread of medical knowledge in the shape of prophylaxis, were set down as potent factors in the impending depopulation, and these were both attributed to medical influence by the rather hysterical French press. As to the first, the evil probably exists in no greater proportion here than elsewhere; as to the second, the French disinclination to have large families has led to the filtration of Neo-Malthusian doctrines from the higher classes to the lower, so that now a family of more than three in the city is a marvel. "France," as remarked a recent writer whose work attracted a good deal of attention, "is a country of only sons who do not marry."

The wealthy do not care to have large families because *Madame* cannot afford the time and *Monsieur* cannot afford the money to dower his daughters, and neither wish to be compelled to divide the patrimony among more than two or three. The poor, who, as it is, find it hard enough to get along in the overcrowded cities, have learned the lesson from their betters, or at least their superiors in caste and intelligence. Only a few of the middle class, the despised *bourgeois*, have more than four in the family and *Voila! la France que commence a depopuler!* It is wrong to attribute anything of this state of affairs to the medical profession, or to ideas that originate with its members. The fault lies, not with any particular class or profession, but in that profound disregard for details in practical social morality which has so deeply invaded all classes in France.

And now come the remedies for the social disease. Not very promising ones, verily. Sumptuary laws for the remittance of taxes on families with more than a certain number of children have been advocated. Then a proposal has been made, which is very popular, to the effect that the state should assume the expense of the education of all children more than three in number in a family. A series of suggestions, drawn from the famous laws of Augustus, when the same state of affairs existed in imperial Rome, have also been brought forward. Everyone knows how ineffective were the Augustinian decrees, and one need not be a prophet or the son of a prophet to tell what the result will be here. The evil lies deeper in the body politic than these superficial remedies can reach. Meanwhile, for other countries there is the practical lesson of the result of certain tendencies in our modern civilization, seemingly of slight importance as yet, but surely impending, and which the medical profession, owing to its intimate relations with family life and affairs, would seem to have a special duty to avert as far as is possible.

A good deal of medical literature just now is taken up with the discussion of the diagnostic value of the typhoid serum reaction in typhoid fever. Most writers, especially Americans, have agreed in attributing the cause of the reaction to antitoxins present in the blood. It is the presence of products in the blood elaborated by nature in her reactive effort to protect the organism against the bacillus that gives rise to the clumping of the bacilli in the presence of the serum, and this clumping is really a degenerative process. While such was the opinion over here until recently, it is gradually being modified. The reaction has been noted in cases of relapse of typhoid just when the first fever symptoms of the relapse declared themselves. It occurs in all cases at such an early stage that even Widal himself has now come around to the opinion that it is rather a phenomenon of infection than one of protective reaction. This may be even more important than if it were merely a commencing bactericidal action, for while bactericidal phenomena have been studied often enough already, opportunities for the study of infective phenomena have been lacking because of the difficulty of knowing where to look for them.

OUR PHILADELPHIA LETTER.

[From our Special Correspondent.]

SIGNIFICANCE OF THE KLEBS-LOEFFLER BACILLUS IN CHRONIC NASAL DISCHARGES—THE SCHOTT TREATMENT OF HEART DISEASE—UNIQUE SPECIMEN FROM THE STOMACH OF AN IDIOT—OBLITERATED INNOMINATE ANEURISM—RETROPERITONEAL SARCOMA—FLECHSIG'S DISCOVERIES IN CEREBRAL LOCALIZATION—ANTIVIVISECTION SOCIETY "ÉN GARDE."

February 1, 1897.

At a stated meeting of the Philadelphia County Medical Society, held January 27th, Dr. Eugene L. Vansant made a report of the results of a bacteriologic investigation of the nasal mucus of 100 cases of chronic nasal discharge. In twenty-six per cent. of the cases examined, the Klebs-Löffler bacillus diphtheriæ was present. Streptococci and various pus organisms, as well as numerous non-pathogenic bacteria, were found in a large majority of instances. Conjecture was made as to the possibility of a causal relation existing between the presence of the Klebs-Löffler bacillus and the chronic nasal discharge with its attendant impairment of vitality. Discussion of the paper brought out the facts (1) that at present animal inoculation is not required to establish the identity of the Klebs-Löffler bacillus, its morphology and behavior towards media, etc., being sufficient for that purpose; (2) whether the clinical picture be of true diphtheria or of chronic nasal catarrh depends on the *virulence* of the infecting bacillus diphtheriæ in each separate case, due credit being given in each instance to the individual's powers of resistance, rather than to the fact that the infection is due in the first place to the true bacillus of diphtheria, and in the other to the pseudo bacillus.

Dr. Andrew J. Downes exhibited a portable cylinder of acetylene gas for surgical illumination, and a self-retaining double-bladed wire vaginal speculum. Dr. S. Solis-Cohen presented the Schott method of gymnastics in the treatment of heart disease. By a series of gently resisted and restricted gymnastic movements of the trunk and limbs, aided by a course of systematic bathing, the peripheral vessels are stimulated and the heart's action reinforced, the rhythmical muscular contractions entering as an added factor to the pumping power of the heart, and the baths giving tone to the sluggish circulation in the periphery. The history of marked improvement in the patients presented by Dr. Cohen proved beyond a doubt that the treatment carried out by the exercises alone had proved eminently satisfactory. Dr. J. Madison Taylor quoted reports of cases showing the efficacy of this treatment of heart disease, and thought that it might also be of use in the vaso-motor ataxias. Dr. John H. Musser presented diagrams illustrating the decrease of cardiac dulness consequent upon a very limited course of the Schott gymnastics in a severe case of endocarditis with enlargement. In concluding the discussion, Dr. Cohen said that the only contra-indications to the treatment were advanced atheroma, arterio-sclerosis, and aneurism of the aorta.

At a stated meeting of the Pathological Society of Philadelphia, held January 28th, a unique specimen taken from the stomach of an idiotic boy was shown by Dr. Clarence White. It was shaped like a huge cigar, being 5 inches long by 1½ inches in diameter, and was made up of a tightly rolled mass of string, pieces of leather and the like. Curiously enough, the gastric mucosa was practically normal, section showing, however, an increase in thickness of the muscular coat from the futile efforts of the stomach to force the foreign body through the pylorus.

An obliterated innominate aneurism was exhibited by Dr. D. D. Stewart. The specimen was interesting from the fact that a number of years ago Dr. Stewart had inserted 10 feet of fine gold wire into the aneurism, when rupture seemed imminent, and by passing a current of electricity through the wire had caused the formation of a clot, with subsequent obliteration and cure. The patient had died very recently from hemorrhage from the middle cerebral artery.

In presenting specimens from two cases of perforation of the intestine in typhoid fever, Dr. D. L. Edsall adduced the fact that in one case the perforation had occurred during the plunge given in the course of the Brand treatment. During the discussion on the subject the conclusion was arrived at that if the diagnosis of perforation were made before general peritonitis had set in, surgical interference would at least be justifiable.

Dr. W. E. Hughes exhibited specimens showing a perforated duodenal ulcer, and a retroperitoneal sarcoma. Early in the history of the latter case the diagnosis of varicocele had been made, due to the fact that the symptoms pointed clearly toward that condition. The discussion of the case brought out the fact that the condition is always one peculiarly difficult to diagnosticate, also that in some instances a pronounced leucocytosis of the blood is noticed.

Dr. Alfred Stengel presented an amebic abscess of the liver, and demonstrated the presence of the amebæ. Always difficult to fix and stain, Dr. Stengel was able to show, not only the ordinary forms of the ameba, with its vacuoles, but also the peculiar reaching out of the ectosarc before division occurs.

Dr. Barker of Johns Hopkins University, Baltimore, read a paper before the Neurological Society, January 25th, reviewing Flechsig's work and discoveries in cerebral localization. Mentioning his methods of medullary staining as being accurately confirmed by the work done on central degenerations, Dr. Barker gave in detail the areas of the cortex cerebri mapped out by this mode of investigation. The newly discovered portions have mainly to do with sense perception, and occupy but a limited part of the external surface of the cerebrum. They are divided into three parts, the central and larger corresponding roughly to the ascending frontal or ascending parietal lobes, the anterior to the foot of the third frontal convolution, and the posterior to a limited portion of the tempero-sphenoidal lobe. Between the three are the two large association areas of doubtful function.

The American Antivivisection Society held its annual meeting in this city on January 29th. Dr. Matthew Woods, the president, in his annual address, said vivisection was undoubtedly on the increase, as shown by the greater number of experiments recorded in medical journals and by the efforts made by those connected with Pasteur institutes, and certain manufacturers, to create a demand for antitoxins. He recommended that the Society change its method of combating the evil, and search out, under capable medical direction, all varieties of cruel work by vivisectors and give it the widest publicity, mentioning the name and address of the perpetrator in every case.

CAN THE CARDIAC MUSCLE BE STENGTHENED BY EXERCISE?—A SUPPOSEDLY BENIGN POLYP FOUND TO BE MALIGNANT UPON MICROSCOPIC EXAMINATION—ABSCESSES FOR ONE YEAR AFTER INJECTION WITH DIPHTHERIA SERUM.

Hirschfeld discussed the possibility of *strengthening a weak heart by means of exercise* at the session of the Union for Internal Medicine held December 21, 1896. This idea was first advanced by Oertel. It does not apply to cases of valvular affection nor to those hypertrophies which follow luxurious living. In these latter cases partial starvation produces the best result, which explains the benefit derived from milk cures. Zuntz who investigated experimentally the influence of exercise upon the heart found that the increase in power of the voluntary muscles greatly exceeded the increase in power of the heart. In compensatory failures rest is indicated because the patient already has over-exerted his heart. But long-continued rest in old people acts unfavorably, as the physiologically necessary stretching of the heart-muscles is thereby omitted, while, on the other hand, increased bronchitis gives the right heart more work to do. In any case muscular exercise should be increased gradually, while its effect upon the heart, especially in stout people, is frequently observed.

At the session of the Medical Society held December 16, 1896, Falk presented a carcinomatous polyp which had been removed from the posterior wall of the cervix uteri of a woman aged forty-five years. The interest in the preparation lay in the fact that a small portion of the polyp was found upon microscopic examination to be distinctly carcinomatous. The uterus was therefore removed. At the point of attachment of the polyp there was a round-cell infiltration. Otherwise the organ was normal. The importance of microscopic examination of all polyps apparently benign was brought forward.

Gensichen referred to *an unpleasant personal ex-*

perience with Behring's serum. In November, 1895, he fell sick with diphtheria, and in order to hasten his recovery he injected into the left side of his abdomen, under aseptic precautions, a syringeful of Behring's serum, No. 2. Recovery from diphtheria was prompt. During the next three weeks he suffered from a terrible thirst without fever. Then there developed on the left side of his body, from the point of the injection to the axilla, large abscesses. These came slowly to a head, broke, and after a few days healed, while new ones constantly formed. For six months they were confined to the left side and then appeared also on the right side. More than a year later they were still forming, although their intensity had greatly diminished. Gensichen expressed himself as deeply impressed with the evil results which may follow the use of serum, and thought that its prophylactic use should be done away with.

This case called forth a lively discussion. **VIRCHOW**, who examined the pus from some of the abscesses, stated that he had not been able to find any trace of the bacillus of glanders but the pus contained almost a pure culture of staphylococcus. Similar cases of multiple abscesses of a chronic form are not uncommon as a result of infection from dead bodies. He was of the opinion that the infection was due to the injection but not to the serum.

EWALD also mentioned cases in which in spite of antiseptic precautions, abscesses followed injection and continued to form throughout several months.

HEUBNER, BAGINSKY, and **KATZ**, were also of the opinion that this case proved nothing against the use of preventive inoculations of diphtheria serum. Variot and Sevestre had made over four thousand inoculations without any serious results.

London.

TREATMENT OF CANCER BY DRUGS—THROMBOSIS IN TYPHOID FEVER—THE PLAGUE—MALIGNANT PAPILLOMA OF THE KIDNEY—DECREASE OF MALARIA IN LONDON—SURGICAL TREATMENT OF PNEUMOTHORAX—BIRDSHOT ENCAPSULATED IN THE EYE—PAROXYSMAL TACHYCARDIA.

EUSTACE read a paper on *the treatment of cancer by drugs* before the Southeastern Branch of the British Medical Association at a meeting held December 10, 1896. He related a case in which he had treated a rodent ulcer of the side of the nose. The tumor was of six years' duration and had recurred after excision. Chlorate of potash was administered internally, and a saturated solution of the same salt was kept upon the wound. In three days the improvement was remarkable and the ulcer was completely healed at the end of a week. There has been no recurrence in the two years which have since relapsed. Although in no way affecting his preference for the operative treatment of cancer the author thought such instances as these are not to be looked upon as mere coincidences. They ought to be fully investigated and reported.

GOSTLING spoke of *thrombosis in typhoid fever* which he said might occur either as a sequel or a complication of the disease. In the former case the prognosis is much more grave than in the latter. Thrombosis as a sequel occurs most frequently in the external and common iliac and femoral veins, which may be felt as solid cords. The symptoms are pain and tenderness in the region of the vein, with swelling and edema of the limb. The temperature is about one degree above normal. The symptoms subside in a week or ten days.

Thrombosis as a complication gives an entirely different picture. Rigors, which are often repeated, irregular temperature, frequent and irregular pulse, irregular respiration, and a mental condition apprehensive of death are the usual symptoms. Death preceded by coma occurs in the large majority of such cases. The danger in complicating thrombosis lies in the breaking down of the infected clot and consequent pyemia.

CANTLIE addressed the Epidemilogical Society December 18, 1896, on the spread of the plague. His paper has already been published in full in the MEDICAL NEWS of January 23, 1897. In the discussion, Lawson, whose experience in this disease extends to over five thousand cases, said that he had never been able to find plague-bacilli in the soil. He believed that the popular idea that an epidemic among rats precedes each epidemic among men is unfounded. Men and rats are affected simultaneously, but the disease runs a more rapid course in rats than in men.

PAYNE said that the description of these recent epidemics corresponds closely with those in Europe in former centuries. He thought that the practical immunity of India is accounted for by the fact that the isothermal line of 78° only just touches the north of India. It has long been held that a persistent high temperature will stop an epidemic.

At the session of the Pathological Society of January 5th, **DREW** described a *villous papilloma of the kidney, ureter and bladder*, in a man aged fifty-six, who for 3½ years had suffered from renal colic in the left side, and profused hematuria. The kidney was opened but no calculus was found. For 2½ months the wound discharged pus containing epithelium. At autopsy the left kidney was found hydronephrotic from obstruction, due to the villous growths in the renal pelvis, ureter and bladder. The author thought that the growth had begun in the pelvis of the kidney and had subsequently extended downward. Its malignant character was shown by the large lymphatic glands adherent to the kidney and extending upward along the aorta. Secondary nodules were also found in the liver. Drew had collected eight examples of papillomata of the pelvis of the kidney, some which were associated with the presence of calculi.

At a meeting of the British Balneological and Climatological Society held December 9, 1896, **EWART** read a paper on the *decrease of malaria in London.* This decrease has gone on since the end of the eighteenth century, but has been especially marked during the last forty years. The author sent out circulars to all the medical institutions of London, and the answers received gave the clearest evidence of the disappearance for many years past of the "London ague," and of the rarity even of any imported cases. The general conclusion was that ague has been dying out not only in London but also in those country districts previously notorious for their malaria. Various causes have been assigned for this decrease, such as systematic drainage and sanitary reform, as well as the improved hygienic and material conditions of the people. These factors, however, do not entirely account for the present remarkable immunity from malaria which bids fair to be reckoned in England within a few years as one of the extinct diseases.

BLAND SUTTON read a paper on *wandering spleens* at a meeting of the MEDICAL SOCIETY held January 11. The cause of the increased mobility is little understood, but it is noticeable that wandering spleens are most frequently met with in women who have borne children. The effects upon the spleen are (1) engorgement to a varying degree; (2) axial rotation, which if acute causes the same symptoms as occur in acute rotation of an ovarian cyst or in strangulated hernia; (3) atrophy, which occurs if the torsion is sufficient to obliterate the splenic artery. Symptoms due to the traction of the spleen on other organs may also be present. Diagnosis is difficult. A spleen in the pelvis has more than once been taken for a fibromyoma of the uterus. Sutton spoke of splenectomy as an entirely justifiable and highly successful operation. He had collected reports of a score of such operations performed without a death. Attempts made by a number of surgeons to suture the spleen in the left hypochondria showed clearly that this operation is a more dangerous one than splenectomy and that recovery from it is not so prompt. He regarded the spleen as a highly specialized lymph gland and saw no greater objection to its removal than would apply to a mass of enlarged glands. He had never seen in his own cases any evil manifestations follow its removal.

BALLANCE mentioned a case in which the patient rapidly recovered from the immediate effects of splenectomy, but after about ten days began to suffer from moderate pyrexia, quick pulse, anorexia, emaciation, loss of strength, increased quantity of urine, and griping pains in the abdomen. The leucocytes were greatly increased. He had seen the same symptoms in two adult males after excision of the spleen for rupture, while a boy whose spleen he had removed did not present these symptoms. Old dogs suffered similar symptoms after splenectomy but young animals did not. The condition of the blood became normal in his cases in about ten weeks, and ultimately all the patients completely recovered their weight and health. Some of these patients were fed after operation on raw or slightly toasted spleens.

SUTTON could not believe that a diet of spleens could have any effect in relieving patients of the symptoms Ballance spoke of. In none of his own cases had he observed such symptoms. The patients were all thin before operation, but did not show afterward any increase in emaciation.

WEST read a paper on *pneumothorax* based upon three sets of statistics including in all 164 cases with a death-rate of about seventy per cent. The causes of death were three-fold according as it was due to (*a*) the pneumothorax itself, (*b*) the resulting empyema; (*c*) the disease which caused the pneumothorax, namely, phthisis. Most statistics give a percentage of recoveries of not more than ten per cent. The most favorable class of cases includes those in which no effusion takes place and the air is simply absorbed. In the next favorable class, the effusion is serous and may be absorbed without paracentesis. If the effusion is purulent the prognosis is more grave, but recovery is still possible, especially after early operation. Cases of recovery were cited to illustrate these three classes.

DUCKWORTH thought that the presence of pus in the pleural cavity is less harmful than might be expected and he therefore discouraged interference in such cases.

HALL said that rest in bed with the administration of laxatives to prevent straining at stool was the only treatment required.

FOWLER and HUBBARD also advised against operative interference.

WEST maintained, however, that early removal of the pus by modern methods is advantageous in many cases. Good results can no more be expected in neglected pyopneumothorax than in neglected empyema.

CARTER reported to the Clinical Society January 8th a case of *gunshot wound of the eye* in which two pellets of birdshot were retained and incapsulated with preservation of sight. They penetrated the lower eyelid and pierced the sclera below the cornea. Carter saw the case two days after the accident, and after dilating the pupil was able to see that the retina had been wounded. An expectant treatment was pursued and the eye recovered without inflammation or trouble of any sort. He thought that the shot had been sterilized by heat and possibly cleansed by passing through the lower eyelid. Although he did not know of any precise observation as to the temperature of heated missles, as a matter of practical experience he had seen several cases in which heated pieces of metal had penetrated the lens and had remained there as sterile bodies without exciting inflammation. He thought it was always safe to pursue expectant treatment for about three weeks as sympathetic ophthalmia rarely occurred before that time.

HERRINGHAM described a case of *paroxysmal tachycardia* in a girl aged eleven. The attacks, to which she had been subject for five years, began suddenly without apparent cause. They lasted for periods varying from thirty-six hours to thirteen days and always ended during sleep. In an attack the pulse was small and soft and could not be counted. Pulsation of the heart was very forcible and occurred from 240 to 260 times a minute. There was little or no pain. Respiration was rapid but there was no sigh of pulmonary or general edema. During a paroxysm sleep was restless, and did not alter the cardiac rate. The patient was a big, plump, rosy girl, but some enlargement of the heart could be made out, and from the study of this case and of other reported cases, Herringham was inclined to believe that these hearts were structurally unhealthy. In this case treatment by various drugs had utterly failed to prevent the recurrence of the paroxysms. The Schott treatment by baths and exercises proved equally useless, nor did it reduce the size of the heart.

WEST said that almost all of these patients had dilated hearts. He mentioned the case of a policeman who although able to remain on duty during his paroxysms, yet developed at these times cardiac murmurs which could be heard at a distance of two feet.

SOCIETY PROCEEDINGS.

NINETY-FIRST ANNUAL MEETING OF THE MEDICAL SOCIETY OF THE STATE OF NEW YORK.

[Concluded.]

Held in Albany, January 26, 27, and 28, 1897.

[From our Special Correspondent.]

James D. Spencer of Watertown, President.

Second Day—Wednesday, January 27th.

(Morning Session—*Continued.*)

E. K. Dunham, M.D., of New York, discussed the

METHODS OF PREVENTION OF POLLUTION OF WATER.

He said that as the usual streams of water were the natural drains we could not, in practice, exclude contamination from sewage, hence we must destroy it. This is best done by putrefaction, if allowed to take place in the superficial layers of the soil, in contact with an abundance of oxygen.

F. C. Curtis, M.D., of Albany, read a paper on the

LIFE HISTORY OF THE TYPHOID BACILLUS OUTSIDE THE BODY.

He said that the typhoid bacillus is an easy prey to many other bacilli, and its complete extinction in a sewer is only a matter of a few days. There is no ground for belief that these bacilli are present in sewer-air; these germs are not inhaled, but ingested. The typhoid bacillus retains its vitality in running water for a long time, and is not destroyed by freezing.

J. S. Ely, M.D., of New York, discussed the

BACTERIOLOGICAL DIAGNOSIS OF TYPHOID FEVER.

He said that, according to some observers, the typhoid bacillus could be detected in the urine of a typhoid fever patient in at least fifty per cent. of the cases examined. Puncture of the spleen is so dangerous as to be hardly justifiable, but certainly in a large percentage of cases the typhoid bacilli could be found in blood from this source. At present, the serum diagnosis by means of an examination of the blood, offered the best prospect of rendering valuable assistance in diagnosis.

W. P. Northrup, M.D., of New York, read a paper on

TYPHOID FEVER IN CHILDREN.

Referring entirely to children not over two years old, he said that out of 2000 autopsies that he had made on children under three years of age, he had not once met with evidences of typhoid fever, and during twenty-five years not a single case had been recorded among the large number of children at the New York Foundling Asylum. As about 1100 children from this institution are placed out to nurse in the tenements, it was certain that many children must have been exposed to typhoid infection. In the Stamford epidemic of last year he had seen, out of 400 cases there, three undoubted instances of typhoid fever in young children.

W. G. Thompson, M.D., of New York, presented a paper on the

IMPORTANCE AND PRACTICAL METHODS OF DISINFECTION OF EXCRETA OF TYPHOID PATIENTS.

He said that the most generally useful disinfectants for cases of typhoid fever were corrosive sublimate (1–500) and carbolic acid (ten per cent.) solutions. The former was injurious to the plumbing, and unless rendered acid, was liable to be materially weakened by the formation of an albuminate. The bed-pan should always contain some of the disinfectant, and after defecation, the perineum should be cleansed with corrosive sublimate solution. Thermometers, rectal tubes, and enema syringes, should also be disinfected, and the bed-clothing, bath tub, and nurse's hands, should not be overlooked in this connection. The stools should be disinfected for at least ten days after the temperature has permanently dropped to the normal. In the country the stools should either be mixed with sawdust and cremated or buried in a trench four feet deep.

Professor William T. Sedgwick, of the Massachusetts State Board of Health, spoke of several unsuspected sources of water contamination, *e.g.*, bathers using bodies of water used for water supply; carelessness of crowds at picnic grounds bordering on lakes, etc. He stated that whereas formerly typhoid fever was rampant in the city of Lawrence, Mass., now, since the introduction of a municipal filter in the water system this disease had almost disappeared.

Afternoon Session.

J. H. Glass, M.D., of Utica, read a paper on

DOUBLE MURPHY BUTTON ANASTOMOSIS.

He reported several cases in which he had used this device, and asserted that not only his personal experience, but the records of many surgeons showed that no method was so rapid and so certain as that with the Murphy button.

L. B. Bangs, M.D., of New York, reported

SOME CLINICAL CASES OF DISEASE OF THE TESTICLE.

(See page 161.)

B. Farquhar Curtis, M.D., of New York, said that enlargement of the testicle might be due to tuberculosis, syphilis, or a neoplasm. Exploratory incision should be used early in all doubtful cases.

Eugene Beach, M.D., of Gloversville, reported

A RARE COMPLICATION OF ACUTE RHEUMATISM.

A healthy man, immediately after sleeping in a damp room and bed, developed a tender swelling of one testicle. After three weeks he had pain on the outer side of both thighs, and two weeks later a mild cystitis and urethritis. This was followed by an exacerbation of the orchitis, and five days later by a pronounced attack of acute articular rheumatism. Careful investigation failed to show any infection.

H. S. Drayton, M.D., of New York, presented some

NOTES OF CASES IN SUGGESTIVE (HYPNOTIC) THERAPEUTICS.

As a result of years of study, Dr. Drayton said that he had come to the conclusion that the hypnotic state is consistent with man's physiology, and is not a pathological phase of either mind or body; also, that in hypnotic suggestion we have an agency of almost unlimited power in the treatment of many diseases. Reports of several cases were read in illustration.

Dr. Wm. James Morton of New York said that he had learned first of hypnotism from Charcot, and had practised it largely for years, but he had become convinced that it was a most pernicious practice, because it diminished the patient's power of resistance and lowered him both morally and intellectually—in other words, the remedy is worse than the disease.

Dr. Drayton replied that we should employ hypnotism just as we would other powerful and dangerous remedies. It was not necessary to go so far as to break down the patient's will.

A. M. Phelps, M.D., of New York, read a paper on

THE MANAGEMENT OF CLUBFOOT.

He advised that *immediately* after the birth of the child with clubfoot the treatment of the foot should be begun. The foot should be placed by manual force as nearly as possible in the normal position, and held there by means of strips of adhesive plaster and a roller bandage. If a continuance of this treatment fails to effect a cure by the time the infant is three months old, the surgeon should at once operate. The operation should consist in a series of tenotomies, beginning with the tendo Achilles. Every resisting structure should be cut successively until the foot can be *super*-corrected. If only corrected, the weight of the body will cause relapse. Having secured super-correction, the only apparatus needed is a plaster-of-Paris shoe. If it is impossible to super-correct the foot, a machine should be used to aid the hand in correcting the deformity, using, if necessary, a force of 1200 or 1500 pounds. The surgeon should, in these difficult cases, cut the anterior division of the deltoid ligament and the long peroneus tendon. Where there is actual bone deformity, it may be necessary to divide the neck of the astragalus, take a wedge out of the os calcis, remove the cuboid and scaphoid bones, or lastly, to perform Pirogoff's amputation. In 500 cases of "open operation" for clubfoot, he had found it necessary to perform osteotomy in only seventeen cases.

Rectal Discussion.

Joseph M. Matthews, M.D., of Louisville, Ky., opened this discussion with a paper entitled

STRICTURE OF THE RECTUM; ITS ETIOLOGY AND TREATMENT.

He first replied to some criticisms of Dr. Kelsey. He said that every authority now believed that stricture of the rectum originates as a secondary or tertiary formation. He did not believe that stricture of the rectum could occur from the extension of a chancrous process. Undoubtedly stricture occasionally results from inflammation produced by trauma. In an experience of nineteen years with rectal diseases, he had not met with a single case of stricture that could be attributed to dysentery. From a pathological standpoint the rectum could not often be the seat of such a stricture. When a connective tissue stricture had once formed, no amount of treatment would cure it.

Daniel Lewis, M.D., of New York, continued the discussion with a paper on

THE SURGICAL TREATMENT OF CANCER OF THE RECTUM.

He said that in every case of cancer of the rectum one must decide (1) as to the general condition of the patient; (2) the extent to which the adjacent organs and tissues are infiltrated; and (3) what operation is best if complete removal be indicated. Operation, in his opinion, was not justifiable unless there was a good prospect of the disease being completely removed. The disease should not extend above the peritoneal pouch, or implicate the bladder or vagina, or the inguinal glands. The speaker preferred the Volkmann to the Kraske operation, believing it to be less dangerous.

Robert T. Morris, M.D., of New York, discussed

THE PROPER METHOD OF TREATING INTERNAL HEMORRHOIDS.

He presented a condensed classification of the anatomical, pathological, and physiological points involved, and showed that we should not do the Whitehead operation, or the so-called American operation, as it removes the structures carrying the special rectal sense. If primary union were not secured, grave complications would arise from the contracting scar. Injecting piles with carbolic acid or astringents is very dangerous, as septic emboli are liable to be carried to the liver or heart, and the sloughing may be uncontrollable. Crushing methods expose the patient to septic embolism and septic infiltration. The clamp and cautery method was successful in a few expert hands, and was less dangerous, but healing was often tedious. In his opinion the two best methods were, (1) ligation and excision of the pile tumor, and (2) excision of the piles and suture of the incisions. The latter was his favorite method.

George R. Fowler, M.D., of Brooklyn, read a paper on

PROLAPSE OF THE RECTUM,

which will appear in a future number of the Medical News.

Dr. B. Farquhar Curtis said that most surgeons would agree with Dr. Matthews regarding the etiology of stricture of the rectum. He would agree with Dr. Lewis regarding the suitability of operating from below in cases of epithelioma of the anus, but for higher strictures such a method would involve an unnecessary sacrifice of the sphincter.

The speaker stated that the operation of colotomy or colostomy was done for two indications, *viz.*: (1) To overcome obstruction low down, and (2) to divert the contents of the bowel from the ulcerated surface. Fulfilling this second indication resulted, in exceptional cases, in a complete cure of ulceration of the rectum. An improvement—sometimes very marked—almost invariably follows colotomy, but the amount of relief will depend, to some extent at least, upon the temperament of the individual. Without doubt this operation prolongs life in cases of malignant disease; nevertheless, extravagant claims had been made for colotomy in this class of cases. If the mechanical obstruction was so great as to indicate the need of an artificial anus, colotomy should be performed, but only under these circumstances.

Dr. James P. Tuttle, of New York, said that out of his record of 200 cases of stricture of the rectum, sixty-eight per cent. were non-malignant, and about the same percentage of these were non-syphilitic. He had yet to see the proof that a single case of stricture of the rectum can occur without previous syphilitic ulceration. The evidence of such ulceration was to be found in the presence of bluish-white cicatricial tissue just below the stricture. There is no such cicatricial condition in malignant disease. Resection of the rectum is the only safe means of curing connective tissue strictures. From 1885 to 1891, or just after the introduction of Kraske's operation, 500 cases were reported—300 perineal and 200 sacral operations. The mortality then from the former was 16, and from the latter, 19 per cent. From 1890 to 1896, he had reports of 175 unpublished operations in this country. These gave a mortality of 11.5 per cent. by the sacral, and a little over 10 per cent. by the perineal method. The high operations are but little more dangerous than those for disease lower down; the prognosis depends, not upon the height to which the disease extends, but to the amount of involvement of neighboring organs. In operating, he preferred the osteoplastic method, and dissected out the whole gut before opening it.

Dr. Matthews, in closing the discussion, said that a far better method of treating prolapse of the rectum in infants than the use of nitric acid or the actual cautery, consisted in giving a preliminary purge, and then keeping the little one in bed for six days with a dozen strips of adhesive plaster across the nates.

Maurice H. Richardson, M.D., of Boston, presented a paper on

ACUTE INFLAMMATION OF THE GALL-BLADDER.

He said that he had only met with this rare disease five or six times, yet its onset was violent and relief was urgently demanded. The cause is an invasion of the gall-bladder by microörganisms, most commonly the colon bacillus. The source of the infection is probably the duodenum, although the blood is a possible channel. In these cases of acute infection the gall-bladder becomes quickly distended, and assumes a cylindrical shape, and because of this, usually assumes a position in which it escapes the palpating finger.

The symptoms are sudden, severe and paroxysmal pain to the right of the epigastrium, followed by vomiting, diffuse tenderness, abdominal distension, constipation, acceleration of the pulse, and elevation of temperature. The pain is often not exactly in the region of the gall-bladder. The condition may be very easily confounded with appendicitis.

The treatment should consist in immediate operation. The incision should be made about half way between the appendix and the gall-bladder, and the fundus of the latter should be sutured to the edge of the incision. The gall-bladder should then be freely opened, drained, and washed with sterilized water.

In these acute cases the prognosis is grave without interference, but with interference is encouraging.

Dr. A. Vanderveer said that he had met with two of these fulminating cases, and in both he had drained an abscess of the gall-bladder with good result.

Dr. George R. Fowler said that he had operated in three of these acute cases under the belief that he was dealing with appendicitis. In cases where the fistulous opening persists, the only remedy after this operation is total excision of the gall-bladder.

Dr. W. G. Macdonald and **Dr. Wm. R. Howard**, reported similar cases.

James Spencer, M.D., of Watertown, the President of the Society, delivered the anniversary address, taking for his theme

THE COUNTRY DOCTOR.

He said that the country doctor may theorize, but he must ever be practical; not having the benefits of free consultation with eminent brethren in the profession, he must stand absolutely on his own merits. There is no hospital, with its corps of trained nurses to assist him, and no daily papers to herald his successes. Yet his arduous life has its compensations. We all know how pain and terror vanish in the presence of the physician; the most intimate secrets are confided to his keeping, and wounds not only of the body, but of the soul, are laid bare before him. The country doctor must, indeed, be a man of many parts—a drudge, a hero, a martyr oft-times, for the cause he represents. He has a large sphere for usefulness in pointing out to his fellow men how they may best avoid disease. But unless the physician is constantly watchful concerning his own mode of living, it will not be long before he is met with the cry, "Physician, heal thyself."

Third Day—Thursday, January 28th.

Wm. James Morton, M.D., of New York, offered a resolution for

THE ABOLITION OF THE NOMINATING COMMITTEE.

He asserted that members of this committee came to Albany already instructed for whom to vote, and, as a result, the Society at large was slaughtered by machine politics. The resolution was referred to the Committee on By-laws.

Place of Meeting.

O.F. Kintoch, M.D., of Troy, offered an amendment making it obligatory for the Society to meet alternately in New York, Albany, and Buffalo. This was also referred to the Committee on By-laws.

J. B. Ransom, M.D., of Dannemora, read a paper entitled

THE NECESSITY OF NEW METHODS OF EARLY DIAGNOSIS IN TUBERCULAR DISEASE TO CURATIVE TREATMENT.

He said that there was a great need for a harmless but sure test for the presence of tuberculosis in the human being. Among cattle, tuberculin was looked upon as an excellent test. He believed tuberculosis to be a largely curative disease, and one which was, to a certant extent, self-limited. There was no good reason at the present time for believing that the presence of tubercle bacilli justified a fatal prognosis.

The treatment should be prompt and energetic, and carried out carefully, in the full belief that the disease could be cured. The treatment naturally divided itself into: (1) climatic, (2) nutritive, and (3) medicinal. He believed that in a locality for the climatic treatment of tuberculosis there should be not only an equable temperature and pine woods in the neighborhood, but there should be winds of sufficient velocity to keep the atmosphere pure. Damp houses are particularly favorable to the development of tuberculosis. A change of climate is important, if only as a precaution against reinfection. It should be a fixed rule that a tuberculous patient should never return to the environment in which he contracted the disease.

The speaker said that in pulmonary affections cough is largely a matter of habit, and the patient should be instructed to avoid coughing except when the secretions had accumulated to such an extent as to make it possible to expel them by a short muscular effort.

DR. E. F. BRUSH of Mount Vernon protested against the very general assumption by the medical profession that the tuberculin test was a reliable test for tuberculosis in cattle. It was not reliable.

DR. THORNBURY said that Dr. Salmon, who was an authority on this subject, had stated that the tuberculin test was reliable in ninety-nine per cent. of cases in cattle, and the test was universally employed by the United States Department of Agriculture. Personally, he looked upon it as absolute means of diagnosis.

DR. F. C. CURTIS asked if tuberculosis were not more prevalent and attended by a larger fatality in prisons.

DR. RANSOM replied that a fair estimate of the death-rate from tuberculosis in penal institutions all over the world, would be about fifty-five per cent.

GEORGE SEYMOUR, M.D., of Utica, reported

A CASE OF HERNIA OF A SARCOMATOUS OVARY.

The patient was a woman of about forty years of age, the mother of seven children. On November 20, 1896, he had operated upon her, expecting to find an ordinary inguinal hernia, incarcerated, but not accompanied by intestinal obstruction. It was found to be attached by a long pedicle, extending from the body of the uterus within the pelvic cavity, out through the internal ring to the under side and upper end of the tumor as it lay in the inguinal ring. The pedicle was tied with a strong silk ligature. The severed end of the portion left within was sutured with catgut into the internal abdominal ring. The portion of sac was tied with catgut and excised. The tumor was oval, measured 4 inches in length and 8 inches in circumference, and weighed 5¾ ounces. Six weeks after the operation the large ligature of the pedicle had passed out through the sinus, and the wound had closed. Microscopic examination by the pathologist showed the tumor to be a spindle-cell sarcoma of the ovary. The woman is now in apparent good health, and has no pelvic discomfort. Menstruation had recurred twice, and apparently normally, since the operation. The speaker said that he had been unable to find any literature on record of hernia of a sarcomatous ovary. Cystosarcoma was more often mentioned than the other varieties of sarcoma. The case must be regarded as exceedingly rare.

DR. W. G. MACDONALD said that in a considerable operative experience he had seen only one case in which the hernial sac contained an ovary. It was not improbable that a small and ill-developed ovary might become incarcerated in the inguinal canal, and then, as was often the case with an undescended testicle, undergo sarcomatous degeneration. In most cases of ovarian hernia, vomiting was a prominent symptom, and its absence in the case just reported was therefore worthy of note.

The Society then adjourned.

REVIEWS.

TRANSACTIONS OF THE COLORADO STATE MEDICAL SOCIETY. Twenty-sixth annual convention. Denver, June, 1896.

THERE is the usual amount of good material in these Transactions. The articles show progressiveness and a great deal of original research. In addition to the record of the meeting, a list of the members of the Society is also printed.

TRANSACTIONS OF THE FIFTY-FIRST ANNUAL MEETING OF THE OHIO STATE MEDICAL SOCIETY, held at Columbus, May 27, 28, and 29, 1896.

BESIDES the address of the president, Dr. Daniel Millikin, on "A Study in Credulity," this volume contains many suggestive and valuable articles. "The Technic of Laryngeal Operations," by Dr. G. W. Crile; "The Dermatoses Due to Vegetable Parasites," by Dr. W. T. Corlett, and "A Plea Against the Meddlesome Treatment of Acute Gonorrhea in Women," by Dr. M. Rosenwasser, are among the best of many good contributions. To judge from this report, the meeting must have been a profitable one.

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT, U. S. ARMY, FROM DECEMBER 29, 1896, TO JANUARY 4, 1897.

The leave of absence on surgeon's certificate of disability, granted Major William C. Shannon, Surgeon, is extended three months on surgeon's certificate of disability, Fort Custer, Mont.

The leave of absence granted Captain William L. Kneedler, Assistant Surgeon, for seven days, San Diego Barracks, Cal., is extended twenty-three days.

Major William R. Hall, Surgeon, relieved from duty at Whipple Barracks, Ariz., and ordered to Washington, D. C., for duty.

First Lieutenant Irving W. Rand, Assistant Surgeon, relieved from duty at Fort Clark, Tex., and ordered to Fort Huachuca, Ariz., for duty.

THE MEDICAL NEWS.
A WEEKLY JOURNAL OF MEDICAL SCIENCE.

VOL. LXX. NEW YORK, SATURDAY, FEBRUARY 13, 1897. No. 7.

ORIGINAL ARTICLES.

THE DIFFERENTIAL DIAGNOSIS OF VARIOUS FORMS OF MALARIAL FEVERS BY MICROSCOPIC EXAMINATION OF THE BLOOD.

BY ALBERT WOLDERT, Ph.G., M.D.,
OF TYLER, TEX.;
FORMERLY RESIDENT PHYSICIAN AT THE MERCY AND ROSELIA HOSPITALS, PITTSBURG, PA.

To bring some order out of the chaos that surrounds obscure varieties of malarial and other forms of fever, greater exactness of observation is required. When we have one cause and one effect, the conclusion can be easily determined; but when there is a multiplicity of causes giving rise to confused results, the individual causes are often difficult to isolate and establish. We have obtained relatively few facts which can be considered absolute in the life history of the different forms of malarial parasites. That these germs gain entrance to the blood, that they grow at the expense of the corpuscles, that they finally break down the globules, that they undergo segmentation, and that these processes give rise to fever, has been proved beyond any reasonable doubt. Some difference of opinion still exists as to (1) whether there is but one specific type of germ giving rise to all the varieties of malarial fever, or (2) whether there is a different organism for each form. Laveran and the French school incline to the former view, while the Italian school, with Golgi at its head, and the American observers hold to the latter belief.

We should be careful, then, to verify by experience the identification of one type of germ, associate it with a specific fever, vary the circumstances, and confirm that experiment by repeated examinations, in order to present conclusive evidence.

This has been undertaken by Thayer and Hewetson, whose observations have extended over a series of 600 cases. This paper will, therefore, adhere in the main to the words used by them, as well as to the microscopic appearances which they have so accurately delineated. Adopting their classification of the organisms, herewith is submitted as an aid a differential diagnosis of the various forms of malarial parasites as they appear during different periods of their cycle.

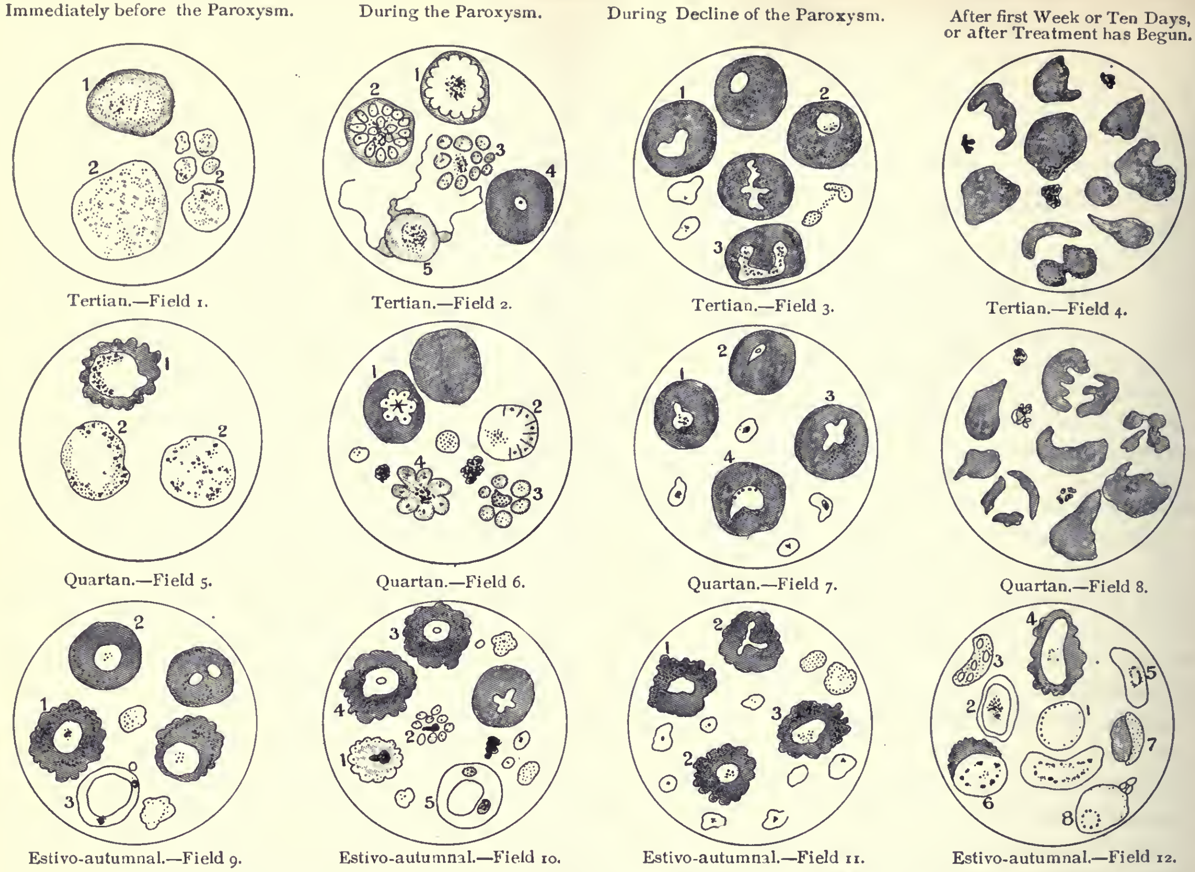
SUMMARY.

The paroxysm is divided into (1) the chill, (2) the fever, and (3) the sweating stage. The chill has no fixed place during the rise of fever; it may occur early or it may only take place at the acme; it usually occurs early in the paroxysm. The *interval* in malarial fevers is the time intervening between the beginning of one paroxysm and that of the next. It is to be distinguished from the *remission* or the *intermission*, which is the period between the end of one paroxysm and the beginning of the next. In quotidian fever the interval is twenty-four hours, and the paroxysms return daily at the same time. In tertian fever the interval is forty-eight hours, and the paroxysms return every other day at the same hour. In quartan fever the interval is seventy-two hours. In the tertian form we predict that a paroxysm will occur at once if radiating lines are seen to appear with the concentration of the pigment in the center of the ameboid cell.

The administration of quinin makes it difficult and often impossible to find the youngest forms of the plasmodia in the blood. It is essential in making a correct diagnosis that the examiner should have a good microscope with an oil immersion lens. No one should undertake the study of pathologic blood without having previously studied normal blood. One type of organism never changes its original type. In order to differentiate the special type of organism, it is best to select the blood during the cold stage of the paroxysm. It can only be identified specifically by having an acquaintance with the different varieties. In this country, the organisms of the estivo-autumnal and tertian varieties of malarial fever are the ones most commonly found, as the quartan occurred only five times in a series of over six hundred cases observed by Thayer and Hewetson.

We differentiate, then, by observing (1) their relative size, (2) the movement of pigment, (3) the color of the corpuscles, (4) the manner of division, (5) by the study of the extra-cellular organisms, and (6) by the contents of the leucocytes.

There may be infections by more than one group of the same kind of parasite, which infection occurs at different times; they will mature at different intervals, and there will be irregular chills and fever; or there may be infections at different or the same time, by different varieties of organisms, also giving rise to irregular chills and fever. In simple tertian fever there is infection by only one group of the same kind of parasite, but if there is a double infection



Immediately before the Paroxysm. During the Paroxysm. During Decline of the Paroxysm. After first Week or Ten Days, or after Treatment has Begun.

MICROSCOPIC APPEARANCE OF THE BLOOD IN THE DIFFERENT FORMS OF MALARIAL FEVER.

Immediately Before the Paroxysm.

Tertian.	Quartan.	Estivo-Autumnal.
1. The organism is now full-grown, pale, indistinct, and ameboid (field 1, Fig. 1). Sometimes fills the entire corpuscle, which has become larger and decolorized. The corpuscle may at this stage be represented by a faint, pale rim about the parasite.	1. The organism, when full-grown, is smaller than those of the tertian type (field 5, Fig. 1), and is more refractive. The corpuscle, instead of being expanded and decolorized, appears smaller, shrunken, and darker in color, often resembling old brass.	1. The full-grown forms are generally not one-third as large as the red corpuscles, which have the same appearance and are crumpled same as in quartan type (field 9, Fig. 1). Some of these organisms are seen to contain a small, central, solid clump of motile or non-motile pigment granules about the center of the hyalin body. At a certain stage (field 5, Fig. 2) it seeks the internal organs (spleen, bone-marrow, etc.), where it undergoes segmentation.
2. Leucocytes do not contain similar blocks of pigment as the estivo-autumnal.	2. Leucocytes do not contain similar blocks of pigment as estivo-autumnal.	2. They are always associated with leucocytes containing similar blocks of pigment (field 9, Fig. 3).
3. Pigment is reddish brown.	3. The pigment is in larger blocks than tertian, and is darker in color.	3. The pigment granules are fewer in number and smaller in size than in the other varieties of parasites.
4. Occasional pigmented bodies may be observed outside of the red cells free in the plasma (field 1, Fig. 2), some of which are twice as large as the red cell, and often undergo gemmation (budding) process.	4. The extracellular bodies are rarely larger than the red corpuscles (field 1, Fig. 2).	4. Extracellular bodies of different sizes and shapes.
5. Some of these extracellular bodies develop flagellæ, usually about twenty minutes after blood has been withdrawn.	5. Extracellular bodies develop flagellæ usually about twenty minutes after blood has been withdrawn from circulation.	5. Flagellation.
6. Period of incubation, ten days.	6. Period of incubation, thirteen days.	6. Period of incubation, three days.
7. Cycle of development, forty-eight hours.	7. Cycle of development, seventy-two hours.	7. Cycle of development, twenty hours or less to forty hours or more.
8. Chills in eighty-eight per cent. of the cases.	8. Of the five cases observed by Thayer and Hewetson, all had chills.	8. Chills in sixty-two per cent. of cases.
9. In twenty-nine per cent. of cases there are more than one group of organisms present at the same time. Double tertian in twenty-nine per cent. of the cases. Out of 542 cases of malarial fevers, sixty per cent. were tertian (Thayer and Hewetson).	9. Out of 5 cases in the 542 observed by Thayer and Hewetson, there was a triple infection in three cases. No double infections.	9. Several groups of organisms are often present at same time. Out of 542 cases, twenty-nine per cent. were estivo-autumnal.

DURING THE PAROXYSM.

Tertian.	Quartan.	Estivo-Autumnal.
1. At the time of the paroxysm, the reddish brown pigment gathers in a clump in the center of the organism, while the rest of the protoplasm looks pale and granular, with radiating lines toward the center. This striation first appears near the periphery (field 4, Fig. 1). These lines become more distinct, until finally the central clump of pigment is surrounded by fifteen or twenty glistening hyalin segments, irregularly arranged (field 2, Figs. 2, 3). This segmentation (sporulation) is always coincident with the paroxysm. At this time we also see similar hyalin bodies within the red cells (field 2, Fig. 4). Segmentation may also occur before the organism is full-grown.	1. The process of the accumulation of pigment in the center of the quartan organism gives pictures which one does not see in the case of the other varieties of parasites, namely, the arrangement of the pigment in a star-shaped form (field 6, Figs. 1, 2), as though it tended to arrive at the center of the body by means of currents which flow inward from the periphery. When the paroxysm occurs, the black pigment gathers in the center in a solid clump, while the protoplasm looks granular; and finally a radial striation occurs, and from six to ten hyalin segments are set free (field 6, Figs. 3, 4).	1. No full-grown organisms are present in the peripheral circulation at this time, and blood must be drawn from the spleen if we desire to see segmentation (field 10, Figs. 1, 2). The advanced segmentary form shows no traces of the corpuscle. Both in the number of segments and manner of division, this type of organism closely resembles the tertian variety. Sometimes, if blood is taken from the peripheral circulation, we may see refractive, oval-shaped bodies situated in crumpled corpuscles having a dark greenish cast. As it becomes larger, there is a small collection of non-motile or slightly motile pigment granules about the center of the body (field 10, Figs. 3, 4). At this time the organism is about one-third diameter of red cell, and has a peculiar homogeneous refractive appearance.
2. Affected corpuscle expanded and decolorized.	2. The affected corpuscle is usually smaller than the unaffected, and the color is darker than normal.	2. The affected corpuscles are not decolorized, but frequently crumpled and in color resemble old brass (field 10, Fig. 3).
3. Leucocytes do not contain similar blocks of pigment as estivo-autumnal.	3. Leucocytes do not contain similar blocks of pigment as estivo-autumnal.	3. These highly refractive organisms with a solid clump of pigment in the center are always associated with leucocytes containing similar blocks of pigment (field 10, Fig. 5).
4. Pigment reddish brown.	4. Pigment darker than tertian.	4. Pigment granules seen in the parasites of peripheral blood usually in one solid clump.
5. In twenty-nine per cent. of the 542 reported cases there was more than one group of organisms present at the same time.	5. Usually several groups of organisms present at same time.	5. Usually several groups of organisms present at the same time.
6. Phagocytosis may be observed by the polymorphonuclear neutrophiles.	6. Phagocytosis.	6. Phagocytosis.
7. Flagellate bodies may be seen (field 2, Fig. 5).	7. Flagellate bodies.	7. Flagellate bodies.
8. Average duration of paroxysm, from eleven to twelve hours. In twenty-nine per cent. of cases of 542 reported, there was a double tertian infection, giving rise to quotidian paroxysms.	8. Average duration of paroxysm ten to eleven hours. Out of the 5 cases observed of the 542 cases, there was a triple quartan infection in 3 instances, giving rise to quotidian paroxysms.	8. Average duration of paroxysm, twenty to twenty-four hours. Quotidian paroxysms in 39 per cent. of cases; tertian, 6 per cent.; continued fever in 34 per cent.

DURING DECLINE OF THE PAROXYSM, OR AFTER THE COLD STAGE.

Tertian.	Quartan.	Estivo-Autumnal.
1. Fresh, round, hyalin bodies are seen within the red corpuscles, with a depression in the center (field 3, Figs. 1, 2, 3). Similar extracellular hyalin bodies are also seen.	1. Color is somewhat more refractive than tertian type (field 7, Figs. 1, 2). Extracellular hyalin bodies seen (Figs. 5, 6, 7).	1. Hyalin bodies somewhat smaller in size than in the tertian and quartan (field 11, Figs. 1, 2).
2. The ameboid movement is very active, quickly changing to ring-shape, etc.	2. First stage of the growth is same as in tertian, except that the ameboid movement of the organism is slower, less extensive, has a sharper outline, and is more refractive than tertian (field 7, Figs. 1, 2, 3).	2. First stage of growth, same as other varieties, is more refractive than the tertian type, and may have a ring or cross shape (field 11, Fig. 2). Body with cross shape may suddenly expand half over the corpuscle, losing its original shape.
3. Affected corpuscle often larger in size and often decolorized.	3. As the parasite grows, corpuscle not decolorized.	3. Affected corpuscle normal in color until later.
4. Pigment (after a certain time) in small granules of a reddish brown color, and very actively moving, breaking into fragments.	4. Pigment (after a certain time) is in larger clumps, darker in color, and, instead of being very active, is only slightly moving. Fragmentation of pigment slower.	4. Pigment not so large in number as tertian, and is finer than quartan.
5. Full-grown forms undergo segmentation.	5. Some of the full-grown forms do not segment, but undergo certain changes. The pigment, which is seen during paroxysm to be slow in action, will be seen to move rapidly, while the body may expand to a size larger than a red cell. These bodies are very transparent, and closely resemble the analogous forms of the tertian type.	5. Segmentation occurs in spleen.

During Decline of the Paroxysm, or After the Cold Stage.—*Continued.*

Tertian.	Quartan.	Estivo-Autumnal.
6. Besides these forms we see large extracellular pigmented bodies twice the size of red cells. These may often be seen to break up into smaller bodies (segmentation?), while at other times they may show a long, tail-like, non-motile process containing sometimes a few pigment granules (field 3, Fig. 4).	6. Same as tertian (field 7, Fig. 4).	6. Several groups of organisms often present at same time, but we will not see the large extracellular forms observed in the other varieties.
7. The large extracellular forms may become fragmented. A small prominence will be noted upon one side of the body, which rapidly becomes shut off from the larger portion, forming a separate pigmented body. In this manner, one large form may give rise to four or five smaller bodies.	7. The full-grown form (field 7, Fig. 4) may undergo fragmentation.	7. Seen during first week or ten days, etc., (field 12, Fig. 1, 2, 3, 4, 5).
8. Vacuoles may be observed in these large extracellular bodies (field 3, Fig. 5).	8. Vacuoles may be found in these full-grown bodies.	8. Seen during first week or ten days, etc.
9. Flagellæ may be developed from the extracellular bodies.	9. Flagellæ may be developed from these full-grown bodies.	9. Seen during first week or ten days, etc.
10. Flagellate bodies may undergo fragmentation.	10. Same as tertian.	10. Seen during first week or ten days, etc.
11. Phagocytosis.	11. Phagocytosis.	11. Phagocytosis.

Several Hours After the Paroxysm.

Tertian.	Quartan.	Estivo-Autumnal.
1. The organisms which were seen during decline of the paroxysm within the red cells have increased in size and contain a few reddish brown pigment granules, which dance actively under the eye (field 4, Fig. 3). The extracellular bodies seen in decline of paroxysm somewhat larger in size.	1. Organisms slower in growth and are not so large as in tertian type; ameboid movement not so active; rods and clumps of pigment are larger and darker in color than tertian.	1. Organisms somewhat smaller in size than other varieties. Fever often continuous.
2. Corpuscle somewhat larger and decolorized. (Parasite always grows at expense of the corpuscle.)	2. As the parasite grows and the pigment increases in quantity, the red corpuscle does not become decolorized as it does in the tertian variety, but the affected corpuscle may be little smaller and darker in color than its unaffected neighbor (field 8, Figs. 1, 2, 3, 4).	2. Color of corpuscle often shrunken or crenated and darker in color.
3. Pigment granules extremely active and breaking into fragments. Organism very active.	3. Pigment granules less active, darker in color, and in larger clumps than in tertian type. Organism slow in action.	3. Pigment granules not as numerous and active as tertian variety, and are finer and not so dark as quartan.
4. Organism hyalin in color.	4. Organism more refractive than tertian.	4. Parasite hyalin in color.
5. Extracellular bodies may give rise to flagellæ.	5. Flagellæ.	5. Flagellate bodies.
6. Phagocytosis.	6. Phagocytosis.	6. Phagocytosis.

Day Between the Paroxysms.

Tertian.	Quartan.	Estivo-Autumnal.
1. The small hyalin bodies seen in the first stage (during paroxysm and decline of paroxysm) will be found to have grown until they half fill the red corpuscle.	1. The organisms seen in first stages of their growth (during paroxysm and decline of paroxysm) are of slower growth and smaller than tertian type.	1. Several groups of organisms often present at same time, giving rise to continuous fever, with daily paroxysms; and we will then see these organisms in the different stages of their growth. The fever is apt to be persistent. Tertian intermittent paroxysms (three per cent.) may occur by infection of this variety of parasite.
2. Corpuscle larger than normal and decolorized.	2. Corpuscle, instead of being expanded and decolorized, appears smaller than normal, darker—often having a greenish, brassy appearance.	2. Color of corpuscles brassy and crenated if infected by larger forms of parasites; pigment granules lie near the periphery in the larger forms, and we may see ring-shaped bodies, which are the smallest size observed. At end of first week or ten days, if no quinin has been taken, we will see ovoids, crescents, etc. (field 12, Figs. 3, 4, 5).

DAY BETWEEN THE PAROXYSMS.—*Continued.*

Tertian.	Quartan.	Estivo-Autumnal.
3. The organisms are still actively ameboid and the number of reddish brown pigment granules has considerably increased.	3. Index of refraction greater than tertian type, ameboid movement slower in action, and the pigment granules, instead of being reddish brown, are larger and darker in color than tertian.	3. Parasites hyalin in color.
4. Pigment granules reddish brown and very active.	4. Pigment granules darker in color, occur in larger clumps, and not so active as tertian.	4. Pigment granules smaller and fewer in number than other varieties, and the movement of the pigment is very slow.

AFTER FIRST WEEK OR TEN DAYS, OR AFTER TREATMENT WITH QUININ HAS BEGUN.

<table>
<tr><th>Tertian.</th><th>Estivo-Autumnal.</th></tr>
<tr><td>1. The small hyalin bodies quickly disappear after quinin has been given.
2. No round bodies, ovoids, or crescents can be seen. Here are shown poikilocytes observed by author in hemaglobinuria and other varieties of malarial fevers (field 4).</td><td rowspan="3">1. The small hyalin bodies have disappeared. Generally all forms of organisms are gone.
2. Certain characteristics and easily-recognized forms may be seen, however, which are only seen in this type of fever, (field 12). These are round or ovoid bodies about the size of a red corpuscle (slightly smaller or larger), with clear, rather highly refractive, waxy-looking protoplasm, and coarse, dark, pigment granules, which are usually collected in rods forming a ring or mass in the center of the organism. The coarse granules may be slightly motile if separated. In association with these are seen crescentic bodies, the protoplasm of which shows the same characteristics as that in the ovoid forms, while the pigment is collected in the middle in a ring or bunch, and which are only slightly motile. Sometimes the crescentic or ovoid body may be in the middle of the cell. More often the remains of the corpuscle are attached to the concave body of the crescent, while in some cases no remains of the cell can be found. Ovoid bodies have been seen to change into crescents, and crescents into ovoids. Segmentation has never been observed in ovoids or crescents.
3. Ovoids may undergo a gemmation (budding) process.
4. Crescents may be vacuolated.
5. When the round bodies occur, flagellæ may be developed from them, and the pigment is very active.
6. All these forms of estivo-autumnal type are the ones usually found in cases of pernicious malarial fever, chronic malarial cachexia, remittent malarial fever, malarial hemaglobinuria, and obstinate cases of malarial fevers in general.</td></tr>

two sets of organisms become mature on successive days, and quotidian fever will occur. This happens in thirty per cent. of the cases of tertian infection. Should there be a double infection of the tertian parasite, one may change the quotidian type of fever into a tertian by giving a moderate dose of quinin before or early in the paroxysm. This is made possible by the fact that an entire group of organisms may be killed at the time of their segmentation, while a half grown set of parasites will continue in its course of development.

The Treatment of Infectious Nephritis by Tincture of Cantharides.—MYSZYNSKA (*Revue de Therapeutique*, January 1, 1896,) concludes from a number of observations that the tincture of cantharides is very useful in the treatment of acute epithelial nephritis either with or without edema, especially in young persons at the beginning of the disease. Under these conditions it is a remarkable diuretic, and decreases the amount of albuminuria even if the patient is not placed upon a milk diet. It also improves the appetite and the feelings of the patient. The dose is from 9 to 12 drops. It is contraindicated in interstitial nephritis occurring in alcoholic individuals and in those whose arteries are sclerosed.

Nocturnal Cough Accompanied by Vomiting in Infants.—GASTOU (*La Médecine*, December 26, 1896,) has seen a number of cases of spasmodic cough occurring in young infants in the night time and giving rise to vomiting. Auscultation gave no clue to its origin. Such a cough has often been attributed to a reflex, set up by the intestinal tract, or by some other cause, while a more thorough examination would have shown it to be due to a posterior coryza. It possesses the following characteristics: It is spasmodic, like the whooping-cough associated with vomiting, and occurs at night—almost never in the day. It is seen in young infants who neither blow their nose nor spit. The result is evident. The secretions from the nose, when the infant is lying on its back, drain into the pharyngeal and arytenoid regions and provoke a spasmodic and strangling cough. The treatment is simple. A bit of absorbent cotton is drawn to a point and smeared with borated vaseline and inserted deep into each nostril. The infant sneezes and snuffs and the vaseline penetrates the nasal cavites as far back as the pharynx. If desired, astringent substances, especially antipyrin, may be mixed with the vaseline. This treatment should be carried out three or four times a day.

PLEURISY; ITS DIAGNOSIS AND TREATMENT.[1]

By R. C. M. PAGE, M.D.,
OF NEW YORK;
PROFESSOR OF GENERAL MEDICINE AND DISEASES OF THE CHEST AT THE NEW YORK POLYCLINIC; MEMBER OF THE NEW YORK ACADEMY OF MEDICINE, COUNTY MEDICAL SOCIETY, PATHOLOGICAL SOCIETY, ETC.

ALTHOUGH pleurisy is of such common occurrence, especially at certain seasons of the year, and the diagnosis, as well as treatment, is regarded usually as a matter of course, I respectfully call attention to the subject this evening in the hope that a full discussion may elucidate any points that may be exceptional to the general rule. In order to do this properly, however, it may be necessary to go over a certain amount of well-known ground.

Let us look, in the first place, at the classification and varieties of pleurisy. The disease in question may be properly defined as inflammation of the pleura, and of two classes: (1) Pleurisy *without* effusion, also called dry pleurisy, circumscribed pleurisy; and (2) pleurisy *with* effusion.

Each of these classes may be one of three varieties: (1) Acute, (2) subacute, and (3) chronic.

Of dry pleurisy, or pleurisy without effusion, little need be said. It is usually secondary, and in that case is located at the seat of the primary trouble, be it a fractured rib or other surgical injury, or inflammation that has extended to the pleura from the lungs, for instance, as in the course of phthisis. It may, however, be primary or idiopathic, and then, for some reason not clearly known, is situated near one nipple or the other, but more frequently the left. The physical signs are few. On inspection, if there be much pain, we observe a "catch in the breath." Palpation and percussion both yield negative results. Finally, on auscultation, the respiratory murmur is only changed in rhythm, the vocal resonance is unaffected, and as for adventitious sounds, a slight crepitation at most is all that may be expected, and even that is not always present. Such physical signs are what might be expected if we consider the pathological condition. The subserous basement membrane may be thickened at some spot, owing to proliferation of the connective tissue corpuscles, or else, with or without such small spot of thickening, there may be on the serous surface a small amount of fibrinous exudation without serum. This would give the crepitation on auscultation. It would not infrequently terminate in a point of adhesion—a condition often observed on *post-mortem* examination in cases of death from various causes, showing that the patient may have had dry pleurisy during life without even having been aware of that fact.

The *diagnosis* of dry pleurisy is readily made, as a rule. The two affections with which it is most likely to be confounded are pleurodynia and intercostal neuralgia.

Pleurodynia, or muscular rheumatism of the side of the chest (called lumbago, in the back), presents for examination a somewhat diffused area of tender muscles in the side, very painful on pressure or the slightest movement. Lumbago is frequently present or alternates. The rheumatism changes also from one set of muscles to another. In the intercostal neuralgia, the pain follows the line of the affected nerve, and is especially painful where the latter leaves the spinal column, in the middle of its course, and at its anterior extremity, for the reason that the nerve is more superficial at these three points, and consequently more tender on pressure. The pain in dry pleurisy, on the contrary, is limited to one spot that may be covered with the point of one finger, and is not increased by pressure or motion except that of respiration.

Let us now examine the other class of pleurisy, or pleurisy with effusion. The effusion is a sero-fibrinous exudation. The more acute the disease, the more fibrin will there be in proportion to the amount of serum. And, on the contrary, as the disease is chronic, so is the serum greater in amount proportionally to the fibrin. There are three varieties of pleurisy with sero-fibrinous effusion: (1) Acute, (2) subacute, and (3) chronic.

Chronic pleurisy with effusion has usually been classed by authors with empyema or pyothorax, also called suppurative pleurisy, all other varieties being termed acute or subacute. To the author there seems to be no good reason for such an arrangement. It appears to be a much better plan to speak of acute, subacute, and chronic pleurisy with sero-fibrinous effusion, and of empyema or pyothorax under a separate head. Acute and subacute pleurisy with effusion may be considered as of the same nature—that is to say, originating in the same way, as exposure to cold, pleurisy *a frigore*, as it is called, rheumatic pleurisy, and so on.

Chronic pleurisy with effusion, according to my experience, has generally been of tubercular or cancerous origin. Landouzy of Paris, as long ago as 1887, claimed that *all* cases of pleurisy with effusion, however acute, were of tubercular origin, and that there was, in fact, no such disease as pleurisy *a frigore*. While this may be true for the climate of Paris, it is certainly not the case in such cities as London and New York, as amply verified by inquiry on this subject at the Brompton Hospital in London and statements of pathologists in New York.

The truth is that acute and subacute pleurisy in this climate may be not infrequently considered as cases of pleurisy *a frigore*, the difference arising from the condition of the patient at the time of attack. Or sometimes, from improper hygienic surroundings and conditions, and lack of care in general, an acute attack may become subacute. More rarely by far may an acute pleurisy with effusion become chronic. The rule is that chronic pleurisy with sero-fibrinous effusion is a chronic disease when first observed, and usually is of tuberculous origin, sometimes cancerous. According to the late Dr. Bowditch of Boston, the pleurisy is of cancerous origin if the effusion into the pleural sac is bloody, as evidenced by aspiration. My experience in this direction leads me to believe that the statement is generally correct. Of course those cases are exceptional when, through accident or carelessness, an intercostal artery is punctured, or the opposing pleura and lung are wounded and injured sufficiently to give rise to an appreciable amount of hemorrhage.

---

[1] Read before the New York County Medical Society, January 25, 1897.

The physical signs of pleurisy with effusion are well known. Suffice it to say that the fluid collected in the pleural sac displaces the lung and acts as a diaphragm or partition to intercept sound, so that over the site of the fluid the vocal fremitus is diminished or absent; so is the respiratory murmur and vocal resonance. Exceptionally, a string of adhesion or rib may telephone or transmit such sounds to some spot with corresponding bronchial breathing and the like. Palpation in this disease is of the greatest importance. The diminution or absence of fremitus, even though bronchial breathing be present, is significant. In cases of doubt, however, the aspirating needle may be tried. The physical signs of acute pleurisy in this first stage are of little import, except the "catch in the breath" observed on inspection and the friction sound heard on auscultation. This friction sound disappears when the effusion takes place in amount sufficient to keep the two pleural layers apart. But in the third stage, after the absorption of fluid has proceeded far enough to allow the two layers to come in contact again, the friction sound returns, or is *frictio redux*. The physical signs of thickened pleura are generally the same as those of pleurisy with effusion, except to a less marked degree.

The *diagnosis* of pleurisy with effusion is usually regarded as very easy to make. That is quite true. But there are some exceptions to which I wish to call your attention. Thus, in a case observed at Bellevue Hospital some years ago, there were all the signs of pleurisy with effusion. There was diminished respiratory expansion on the affected side, absence of fremitus on palpation, marked dulness on percussion, if not flatness, and absence of respiratory murmur. The vocal resonance was also diminished or absent. The case was regarded as one of pleurisy with effusion until *post mortem* examination revealed occlusion of the left primitive bronchus, due to presence of an unobserved aneurism. There was complete obstruction to convection of sound in the left bronchus, thus cutting off the respiratory murmur, fremitus, and the like, giving the same result, but in a different way, as in pleurisy. Meantime the whole left lung became filled with a mucoid fluid, giving rise to the marked dulness on percussion. Walshe mentions a case where enlargement of the heart has been mistaken for pleurisy with effusion.

Enlarged liver or spleen may sometimes be readily mistaken for pleurisy with effusion, but the well-known differential physical signs are generally sufficient for a diagnosis without the aid of the aspirating needle. Sometimes, however, the spleen enlarges upwards instead of downwards, as Niemeyer very properly observes. In some of these cases the needle has to be used to make the diagnosis, as was perfectly illustrated in the case of a young man whom I took for advice to the late Drs. Leaming and Hudson.

In differentiating pleurisy from solidified lung tissue, a subject that presents difficulties in some cases, the curved line of Ellis has been regarded by some as of much importance. That is to say, that the upper surface of the fluid in the pleural sac is not a level, as is the case with fluids in general, but higher at some points than others, and presenting a line of dulness just the reverse of the direction of the interlobar fissure. I must confess that I have never found this curved line of Ellis to be, of itself, of any practical value in making a diagnosis—even admitting that it exists, nor have I ever heard it satisfactorily explained.

The *prognosis* of the disease depends greatly upon whether it is the ordinary acute primary pleurisy, or whether it is secondary to some other disease. In the first case, the prognosis may be said to be very favorable under proper management. The rule is recovery in two or three weeks after the attack commences. When secondary, it depends, of course, on the primary condition, of which the pleurisy is only a symptom or complication.

The *treatment* of acute pleurisy with sero-fibrinous effusion is generally directed first to the pain in the side. How are we to afford relief? Perhaps the simplest way would be to administer an opiate; in fact, if the pain is very severe, this will have to be done. The hypodermic injection of a moderate dose of morphin, to be repeated, if necessary, at proper intervals for the first day or two, may be all that is necessary, since it is only during the first few days that pain is an urgent symptom. In many cases morphin is not required. Dry cups have been highly recommended, but in my experience they are of little service and cause much annoyance to the patient. In case opium is not required, or even in conjunction with it, the question lies between hot and cold applications. Of these, I do not hesitate to recommend the hot-water bag in preference to ice. It affords greater and more speedy relief than ice, and to the patient is much more comfortable. Hot applications, with or without opium, therefore appear to be the best remedies for the pain in the side.

The temperature in pleurisy rarely goes so high as to require interference, but should it be thought advisable to reduce it, a moderate dose of acetanilid or ammonol—say three grains—can be given at noon and repeated at intervals of three hours until bedtime. This is a much better plan than administering quinin, unless a positive malarial condition is present, for, with the exception of controlling temperature in malarial affections, quinin is of little or no benefit, and often does harm by increasing head symptoms, such as delirium, insomnia, deafness, and the like.

Remedies to control the pulse can be given in pleurisy with far less danger of fatally depressing the heart than in pneumonia. For that reason, veratrum viride, aconite, and similar medicines can be used not infrequently with great advantage, whereas in nearly all cases of croupous pneumonia they are, in my opinion, out of the question.

As a rule, in ordinary favorable cases of acute pleurisy with effusion, stimulants are not needed, but the physician would be guided in this as in other diseases, by the character of the pulse, the patient's general condition and previous habits. In ordinary cases, when stimulants are called for, as evidenced by the dry, brown tongue especially, a tablespoonful of whisky or brandy in a little milk every three hours is sufficient; but among those addicted to intemperance a much larger quantity has to be administered. Digitalis, which is so highly recommended and often urgently needed in pneumonia, is seldom required in pleurisy, and the same may be said of nitroglycerin, carbonate of ammonia, and other so-called heart stimulants, the alcohol alone usually being quite sufficient.

Even to this day it is a common practice with the profession at large to apply blisters both in pneumonia and pleurisy. I cannot help disapproving of such practice, however common it may be, in the acute stages of these diseases. In acute pleurisy, blisters would not only do no good during the first two weeks, say, but would do positive harm by interfering with the patient's comfort, and also by increasing the rise of temperature. Should the case become tedious and the effusion remain stationary after the third week in spite of ordinary treatment, then blisters and other counter-irritations, as by means of the tincture of iodin, compound iodin ointment, and the like might be tried, though even here aspiration would be better.

To cause the absorption of the effused liquid in the pleural sac in acute cases, the best remedy I have ever tried is sodium salicylate. It may be given early in the disease, and in the same doses as in acute articular rheumatism. In fact, if we regard the pleural cavity as a large joint, there is no reason why it should not be subject to rheumatic inflammation and effusion, as the knee, for example, in acute rheumatic fever, and in some of these cases the sodium salicylate does certainly act speedily and effectually. On the other hand, I have observed but little benefit derived from the administration of iodid of potassium or such diuretics as acetate of potash with infusion of digitalis, diuretin, and so on. Such remedies do more harm by interfering with digestion and nutrition than any benefit to be derived from their use. But the sodium salicylate should be given with proper precaution. In some cases it so depresses the heart and causes such vertigo that its further use has to be discontinued at once. Also, if such symptoms do not arise so as to contraindicate its further use, it may just as well be discontinued after a few days or a week if such trial proves its action to be of no benefit.

An all-important question arises in the treatment of pleurisy with effusion: Shall we aspirate, and if so, at what stage of the disease, and at what point shall the needle be inserted?

In order to discuss this question properly, let us refer again to the three stages of acute pleurisy with effusion: (1) The dry stage, lasting only a few hours; (2) the stage of effusion, lasting usually from five to eight days; and (3) the stage of absorption, the whole duration being two or three weeks.

Of course, it is generally agreed that if the fluid has accumulated rapidly, as sometimes happens, and is excessive in amount, aspiration should be resorted to at once. Not only is life endangered by asphyxia from interfering with respiration, but if the heart be much compressed, as evidenced by its wide displacement and feeble and irregular beats, the patient may die very suddenly from heart failure. Under such conditions, aspiration alone can save life, and it should not be delayed.

Generally about half the fluid is withdrawn. That is usually sufficient to relieve the urgent distress. Moreover, the cough and pain in the chest caused by the expanding lung will now interfere greatly with further withdrawal of fluid, not to mention the danger of rupture of the lung. In a few days the fluid may have returned, and a second or even a third aspiration may become absolutely necessary. After this, in favorable cases, the exudation of fluid ceases, and what is left in the pleural cavity becomes rapidly absorbed, with complete recovery. But unless such urgent symptoms do present themselves—in other words, if the patient be doing well, are we to withdraw the fluid during the acute stage? Certainly not. The reason for it is obvious. There is a great tendency to the formation of adhesions in pleurisy under the best conditions. To draw off this fluid during the active stage of inflammation, as evidenced in part by the pain and temperature, would simply bring the inflamed surfaces together that had heretofore been kept apart by the effusion. Increased irritation with a more severe grade of inflammation would follow, and, extending into the subserous connective tissue, would convert a superficial into an interstitial exudation and result in a thickened pleura, if not extensive plastic adhesions. Such a termination would be extremely unfortunate, and due to unnecessary if not meddlesome interference. Both lungs would be damaged, the one from imperfect expansion due to such thickening of the pleura and extensive adhesions that hill-climbing or the use of the pneumatic cabinet would fail to break them up; the other from vicarious emphysema, in its effort to do compensatory work. It is to avoid these injuries to the pleuræ, with consequent permanent injury to the organs of respiration, that Potain and other eminent authors so earnestly recommend that, in ordinarily favorable cases, the operation be not resorted to before the second or third week, when all signs of active inflammation have subsided.

It has been recommended that the early withdrawal of the fluid might be practised while injecting sterilized air, thus converting acute pleurisy with effusion into acute pneumothorax; in other words, to substitute sterilized air for fluid as the medium for keeping the two serous inflamed layers apart. The air would become more rapidly and certainly absorbed, while, at the same time, remaining long enough to prevent the injury that would otherwise result from the immediate contact of the inflamed surfaces and sudden expansion of the lung. But, as yet, I have never learned that any practical result for good has been reached by such means. There is no danger whatever, in my opinion, that a sero-fibrinous effusion will be converted into a purulent one by the operation of aspiration if proper precautions, now so well-known to the profession, are observed. But if drawing off the fluid is not good practice, allowing it to remain too long may be said to be equally bad. In this case the period of active inflammation is over, the stage of organizing has arrived, and if the lung be allowed to remain compressed and quiescent, adhesions are almost certain to result.

It is difficult, however, to lay down precise rules for thoracentesis, but Anstie's summary of indications is as good as any, and very convenient. He recommends the operation:

1. In those cases where the fluid fills one pleural cavity and begins to compress the heart and other lung.
2. In all double pleurisies where the total fluid would about fill one pleural cavity.
3. In cases of even a moderate amount of effusion, but attended with paroxysms of orthopnea.
4. In all cases where the fluid is purulent.
5. In those cases where the fluid, occupying at least half of a pleural cavity, has existed for several weeks, and shows no signs of being absorbed.

Though thoracentesis was performed by Troussau of Paris as early as 1830 for evacuating pus from the pleural cavity, to Bowditch of Boston is due the honor (in 1857) of first advocating aspiration in cases of sero-fibrinous effusion. In performing the operation, he preferred the scapular line (Bowditch's line) at a point two inches above the line of the lower border of the healthy lung. One objection to this locality is the accidental plugging of the needle with particles of inflammatory exudation that have settled down at this most dependent point, so that I have been compelled to withdraw the needle and clean it out several times during an operation. For this reason I prefer the axillary line and the fourth interspace on the right side, and the fifth on the left.

In the case of pus in the pleural cavity, a sufficiently large opening should be carefully made at the most dependent point to insure proper drainage; but in case of sero-fibrinous effusion, there is no reason why we should select such a low point, since a sufficient quantity of the fluid may be withdrawn by going higher up. We also avoid the danger of puncturing the diaphragm and going into the abdominal cavity, thereby causing fatal peritonitis. Such an accident could never happen if the operator would only bear in mind the lowest points of attachment of the costal pleural membrane to the chest walls, for they are much higher up than are generally supposed. To avoid unnecessary depth of penetration by the needle and wounding the lung, I invariably use a shield. As soon as the point of the needle is free, showing that fluid has been reached, the shield or guard is slipped down against the chest wall and firmly secured by means of a screw. It is difficult to say just how much fluid is to be withdrawn, but in general about one-half. The operation should cease immediately if there be signs of collapse, as evidenced by feeble pulse, pain across the sternum, and the like.

I have laid a good deal of stress on this subject of thoracentesis, or aspiration, in cases of pleuritic effusion, but no more, in my opinion, than it deserves. The operation itself is so easily performed that it may be almost regarded as insignificant. And yet Potain and other eminent authors of large experience regard it as always to be considered a serious procedure, which should invariably be performed under the necessary precautions. In view of these facts it is difficult to see what grounds there are for much difference of opinion, yet we sometimes find it recommended to draw off all the fluid as soon as the diagnosis is made, while others contend that it is wrong to aspirate before the third week. At present, however, it seems to be customary to perform the operation much earlier than was formerly taught.

In the case of children, the operation is rarely necessary, as the fluid is nearly always absorbed.

Dieulafoix's aspirator is the best instrument to be used, but it costs so much that Potain's aspirator with a bottle attachment is preferred by many. This, however, costs more than there is any necessity for, and, in addition, causes a great deal of continuous pumping to render the bottle a sufficient vacuum for withdrawal of the fluid. For such reasons Potain's fine trocar and canula, with rubber tube attached, simply a siphon, is recommended as one of the best.

For after-treatment, the patient should be sent to a rolling country, where moderate out-door exercise, in addition to hill climbing, will insure full expansion of the crippled lung, thus still farther preventing adhesions, or breaking up those that may have formed. By such means I have known absolute recovery after a very severe attack. The next best plan to hill climbing undoubtedly is the expert use of the pneumatic cabinet. The pulmonary gymnastics afforded by this instrument can hardly be over-estimated. What has been said in regard to acute pleurisy with effusion, applies, with modifications, to the subacute variety. Little or no benefit, however, need be expected in these cases from the use of sodium salicylate; in fact it is generally contra-indicated on account of its depressing influence.

In regard to chronic pleurisy with effusion, the primary disease, of which it is but symptomatic, should be treated. Of these primary diseases, tuberculosis is by far the most frequent.

[For discussion see page 221]

THE AMBULATORY TREATMENT OF FRACTURES OF THE LEG.[1]

BY JAMES PORTER FISKE, M.D.,
OF NEW YORK;
INSTRUCTOR IN ORTHOPEDIC SURGERY AT THE NEW YORK POST-GRADUATE MEDICAL SCHOOL AND HOSPITAL; ASSISTANT SURGEON OUT-PATIENT DEPARTMENT,
ROOSEVELT HOSPITAL.

AFTER the discussion in 1894 in Berlin[2] oi the ambulatory treatment of fractures of the lower extremity, a considerable interest in the subject was aroused, and although nothing really new or novel was offered, still it has caused a somewhat more extended use of this method of treatment. The ambulatory treatment of leg-fractures seems to be regarded by some as new, and by others as merely the adoption of views that first found expression some thirty years ago. The method of which I speak in this paper is in use in the Roosevelt Hospital fracture service and, at the time of its introduction by Dr. John McG. Woodbury, was new as regards certain principles, namely, the time when the patient was instructed to walk on the injured limb, and the locomotion of the patient without the aid of crutches; and in speaking of the ambulatory treatment of fractures, I have reference particularly to the large number of cases in the Roosevelt fracture service treated by us where the patient was allowed and encouraged to walk at once, without crutches or supporting braces other than the protective splint directly applied to the injured member.

The splint used in these cases is the plaster cast, so applied as to extend from the toe-tips up to and around the tuberosity of the tibia, so that in walking the greater portion of the weight of the body is supported by the circumference of the upper part of the cast. After reduction of any existing deformity, the limb being held in the proper position, the splint is applied as follows: Beginning at the toe-tips and extending to the knee-joint, the limb is firmly and smoothly bandaged with an ordinary muslin roller. Over this is applied the plaster of Paris cast. No padding with cotton is made use of, the object being to have the splint exert equal pressure at every point, and so provide absolute fixation. In many cases, as soon as the plaster is perfectly hard, the patient may walk, and walk without any other supporting apparatus. As a rule, however, he is instructed to keep his leg in the horizontal position for twenty-four hours, and if at the end of this time the splint is comfortable and there is no tendency of the toes to swell, he is allowed to walk.

In the treatment of any fracture, there are certain important indications to be borne in mind. The surgeon must (1) reduce the deformity; (2) maintain such reduction; (3) fix the fragments and protect the limb, and (4) attend to the general condition of the patient. The last consideration is of especial importance, and I cannot emphasize too strongly the desirability of keeping our fracture cases out of bed. It applies equally well to children, to adults, and to old men and women. I may cite here the case of a man, seventy-two years of age, suffering from a Pott's fracture, who was up and about on the eighth day after the receipt of the injury, and able to walk without the aid of crutches or cane. These statements apply to all fractures, including even compound fractures when observation of a few days has shown us that no infection exists. In the ambulatory treatment of fractures the general condition of the patient is better maintained, less atrophy of the injured limb takes place, and the stiffness of joints in the neighborhood of the fracture is much less pronounced than in those cases which are confined during convalescence. The questions to be decided in considering the advisability of this method of treatment relate to the selection of cases, the form of apparatus to be used, the time when the patient is first permitted to walk on the splint, the duration of treatment, and the advantages gained and risks incurred.

---

[1] Read before the Section on General Surgery, New York Academy of Medicine, January 11, 1897.

[2] Verhandlungen der Deutschen Gesellschaft für Chirurgie, xxiii Kongress, 1894.

The Selection of Cases for this form of Treatment.—I have never seen a fracture of the leg which at some time during the healing process was not suitable for the ambulatory splint. There are many cases where the accompanying edema is excessive, and others where there is a considerable effusion of blood. In these cases the surgeon should apply equable pressure throughout, fix the fragments, raise the leg, and keep the patient in a recumbent position until the effusion is absorbed and the swelling disappears. The walking cast is then to be applied, and the patient is allowed to be up and about. It is a great advantage to apply the plaster cast immediately after the receipt of the injury, and thus by the firm, even pressure which it exerts to prevent edema or effusion from occurring. I have never met with an instance of a fracture of the leg in which an immediate application of the plaster cast was followed by bad results. In compound fractures the limb should be made thoroughly aseptic, an aseptic dressing applied, and the fragments fixed. If infection does not occur the ambulatory splint is applied later, and the patient then may begin to walk. When there is an extensive injury to soft parts, the patient must be kept in the recumbent position, with the leg elevated, but in these cases the ambulatory splint should be applied as soon as the condition of the leg warrants it.

The Best Form of Splint for the Ambulatory Treatment of Leg-fractures.—The plaster cast is the only one that has been used in the Roosevelt Hospital fracture service, and the only one, in my opinion, that will make the treatment successful. The ordinary cast varies in thickness from one-eighth to one-quarter of an inch, being thickest about the ankle and at the upper circumference where it grasps the head of the tibia. The plaster of Paris used must be of the best quality. At Roosevelt Hospital use is made of two kinds of plaster bandages, one being the ordinary gauze roller impregnated with plaster of Paris, the other a stiff starch bandage similarly impregnated. A layer of the common plaster bandage is first applied, and this is followed by a layer of the starch-plaster bandage; over this is built the cast with the common plaster of Paris bandages. By thoroughly incorporating these bandages into one mass a cast is made which is fairly light and yet possesses some elasticity, due to the starchy element, and so, while it affords absolute fixation, it is very unlikely to crack or break when the patient walks.

The Time when the Patient Should be Encouraged to Walk with the Splint.—In an uncomplicated case, when an immediate application of the cast has been made, before the occurrence of edema, the patient is usually allowed to rest for twenty-four or forty-eight hours, and then if the toes are not swollen, and the splint is comfortable, he begins to walk. At first his gait will be awkward; he may be nervous and afraid to trust his weight on the plaster cast; but with a cane he will soon learn to balance himself, and in a short time he will require no support except that afforded by the splint.

The Duration of the Treatment.—As regards solid bony unions I am of the opinion that in the great majority of cases no time is gained by this method of treatment. The after-treatment is considerably shortened, however, as the remaining stiffness is less and is more easily relieved. The average length of time the splint has been worn is from twenty-eight to thirty-five days. In a few cases it has been worn for six weeks, the time depending on the amount of callus thrown out, and the completion of consolidation. After the removal of the splint, the leg is douched alternately with hot and cold water several times a day, in conjunction with massage, until all stiffness has disappeared.

Advantages of the Ambulant Method.—I have already mentioned some of the advantages of this form of treatment. Briefly, they consist in the fact that the patient is kept up and about, less muscular atrophy occurs, there is less stiffness of adjacent joints, the period of after-treatment is considerably shortened, and the general health of the patient is maintained. It must also be remembered that the chances of hypostatic pneumonia, occurring in elderly patients, are much less if we keep them active. Quite a number of fractures of the leg have been treated in people addicted to the constant use of alcohol, and I have never seen a case of delirium tremens occur when the ambulant splint was used from the first.

Risks Incurred.—The chief risk is incurred during the application of the cast. To properly apply a cast of this kind requires a skilled operator and a skilled assistant. The importance of skilled assistance and intelligent coöperation is just as great to the surgeon in the reduction of the deformities attendant upon fractures, as it is in the reduction of any other bone or joint deformity. The position of the limb, and skill in holding it during the application of the cast, are most important factors in connection with the success of this procedure. In oblique fractures the splint must be worn until the callus has been absorbed and the fragments have united firmly, so that there is no possibility of the upper fragment becoming displaced later on by the weight of the body.

The accompanying statistical table shows the cases subjected to this method of treatment, from the spring of 1888 to September 15, 1896, in the Roosevelt Hospital fracture service, under the supervision of Dr. Frank Hartley and Dr. John M. Woodbury, in the Post-Graduate Hospital service under the charge of Dr. John M. Woodbury, and in the private practice of the writer.

Taking these seven groups of fractures in the order as shown in the table, Pott's fracture will be considered first. In many cases the deformity is so extreme and typical that a diagnosis is made at sight. In other cases, there is no outward displacement, and very little swelling, and a correct diagnosis is arrived at only after a painstaking examination. The existing deformity is usually corrected easily by flexing the foot to a right angle and making extreme inversion. This position must be maintained until the splint has been applied and the plaster has set. Of the 56 cases of Pott's fracture, the ambulatory splint was applied in 38 instances during the first twenty-four hours; in 18 cases the cast was applied from three to twenty-one days after receipt of the injury.

Fractures of the fibula are of very frequent occurrence. A fracture of the shaft frequently shows little or no displacement, and, as a rule, simply requires the application of the plaster cast. Fractures of the lower end of the fibula frequently show some deformity, and may be accompanied by inward or outward displacement of the foot. A fracture of the lower end of the fibula, accompanied by some outward displacement, but where the internal malleolus is intact, should be regarded as an incomplete Pott's fracture, and calls for the same treatment. Fractures of the lower end of the fibula, with some inward displacement, calls for some eversion as well as flexion to a right angle before application of the plaster cast. Out of 110 fractures of the fibula, 101 were of the external malleolus or at the lower third. In 81 cases, the ambulatory splint was used from the first. In the remaining cases of this group, this treatment was inaugurated from two to twenty-three days from the time of injury, the cases including one compound fracture at the middle third of the bone where the walking splint was applied on the fourteenth day.

Fractures of the tibia are more serious, indicating as they do the receipt of greater violence, and may be accompanied by a considerable degree of shock. Many of the simple fractures do not show much dis-

[1] Compound.

[2] Had been compound.

placement, and, as a rule, are readily put up in a correct position by having a good deal of extension made in the direction of the limb during the application of the cast. In the 22 fractures of the tibia, 9 occurred at the lower third, and 13 at the middle third. Sixteen were treated from the first by this method, and 6 from five to eleven days after receipt of the injury, including one compound fracture on the fifth day.

Fractures of the tibia and fibula require the greatest care in putting them up properly. The surgeon must bear in mind the tendency toward a posterior sagging of the fragments during the application of the cast, and considerable extension must be maintained while this is being done. Of the 14 cases of fracture of both bones, 6 were treated from the first by this method, and 8 from the sixth to the fourteenth day. In fractures of the middle third of both bones, when there is a tendency toward displacement of the fragments, the splint should include the knee-joint and extend well up on the thigh. On the tenth day the bones will be pretty firmly glued together, callus will have been thrown out, and ossification will be under way. The splint is then removed, and if the limb is in good order, the ambulant splint is applied, up to the head of the tibia.

The osteoclasis cases, 24 in number, are here considered because many of them have been most perfect examples of the ambulatory treatment of fractures of both bones about the middle third. They also show the value of the immediate application of the plaster cast, applied as it was without padding, and controlling or preventing the occurrence of edema and effusion. It has been a common sight after the first week to see these little children stand and attempt to walk, and after the first week I always encourage them to do so.

The cases of non-union following fracture, 11 in number, which are presented, were of no little interest, as several of the patients had been confined to bed for a considerable period. Not one case of fracture treated by the ambulatory method ended in this unfortunate way. The ambulant splint was applied to these cases, and the patients were encouraged to walk; if union did not occur within a reasonable time, the fragments were thoroughly needled. This method has been very successful.

Two cases of the Trendelenburg-Hartley operation are here considered, as they show the value of the ambulatory splint in compound fractures. On the tenth day, as a rule, the dressing was removed, the stitches taken out, and a new cast applied, and frequently by the fourteenth day the patient was able to walk very well. This is a very good showing when we bear in mind that a good sized wedge had been removed from the tibia and a linear osteotomy performed on the fibula.

In 226 fractures of the leg, the ambulatory cast was applied during the first twenty-four hours in 159 cases, about seventy per cent. of the total number.

In a letter which I have just received from Dr. Frank Hartley, he says: "I believe thoroughly in the ambulatory treatment of fractures, when we exclude from such cases the fractures complicated by injury to the soft parts—arteries, veins, lymphatics, tendons, etc., or severe laceration of tissues from dislocation of rough, bony fragments or joints, where such injuries demand a more careful and special treatment for their relief than is demanded by the fractured bones, as well as in cases in which, from the obliquity of the fracture, the retention of the fragments in position demands more than the ordinary plaster splint. With these exceptions I fully agree with you in the manner of treatment, and believe that the advantages derived from it are a more rapid and solid union of the fragments, an earlier development of function in the limb including the use of the muscles and the mobility of the joints, and the advantages to be derived to the patient from not being detained at home or in a hospital."

ILLUSTRATIVE CASES UNDER TREATMENT JANUARY 11, 1897.

CASE I.—R. I., aged forty years. Slipped on the ice and fractured external malleolus December 19, 1896. I saw him immediately after the injury, and at once applied the ambulatory cast. He was directed to go home and keep his leg raised during the rest of the day. He reported to me the next morning, and as the leg was in good order and the splint comfortable, he was instructed to walk. He has been up and about since. The cast will be discarded at the end of this week.

CASE II.—F. B., aged six years. December 21, 1896, while coasting on the snow he ran into a cart and fractured the tibia just below the middle third. He was taken to the accident room in the Roosevelt Hospital, and the leg was put up in plaster. He came to me one week later, when the dressing was removed, and as the leg was in good condition, the ambulant splint was applied. He reported to me the next day, and as the conditions were favorable and the splint comfortable, he was instructed to walk. In a few days he not only walked with ease, but rode his velocipede daily.

CASE III.—J. R., aged thirty-two years. On January 3, 1897, he fell a distance of six feet from scaffolding and incurred a Pott's fracture. I saw him the next day, and there was then present some edema, ecchymosis, complete disability, and some outward displacement. The foot was inverted and flexed to a right angle, and the ambulant cast applied. He has been able to walk well since. The cast was changed on the third day on account of the subsidence of edema. He will wear the cast for four weeks from the date of injury.

CLINICAL LECTURE.

SUPPURATING LARYNGEAL BURSA; FOREIGN BODY IN THE NOSE: DEFLECTION OF THE NASAL SEPTUM; HYPERTROPHIC CATARRHAL LARYNGITIS.[1]

BY E. FLETCHER INGALS, M.D.,
OF CHICAGO;
PROFESSOR OF LARYNGOLOGY AND DISEASES OF THE CHEST IN RUSH MEDICAL COLLEGE.

CASE 1.—*Suppurating Laryngeal Bursa.*—This man is thirty years of age. Two days ago he noticed a small hemispherical growth, about an inch in diameter, just above the thyroid cartilage. It caused no inconvenience. Dr. Freer found nothing abnormal upon examination of the larynx with the mirror. He had specific trouble some months ago, but no symptoms remain excepting copper-colored patches on the skin. He says he has been having malarial fever for eight weeks past—an affection that is very rare in this city. Upon being questioned he admits that the fever never left him for three weeks, that he was kept awake nights, that he could not eat, and that he had violent headaches, and was very weak. The fever surely was not malarial. The growth is movable. It is apparently just beneath the skin, lying between the notch of the thyroid and the hyoid bone. It seems to fluctuate slightly on pressure. The only tumor that we are liable to find in this region is caused by an inflamed bursa. I have seen but two or three such cases, and I think no one has been able to give a satisfactory explanation for the growth. Although he has only noticed the growth for a couple of days, it may have been there a much longer time without discovery, as it has caused no discomfort. Introducing an exploring needle I obtain pus. It is yellower than usual, but not very thick. Other cases of this character that I have seen have been slow to heal. In this case we will withdraw the fluid and inject a solution of carbolic acid; at first 5 or 10 per cent. strong, hoping to cause adhesive inflammation. In several cases I have stopped the suppuration of an indolent abscess by injecting lactic acid, 30 to 40 per cent. strong, and have had healing take place without an external wound: therefore, if the carbolic acid does not succeed we will try lactic acid. The question arises whether this abscess resulted from syphilitic inflammation of the thyroid cartilage. As there has been no pain there can hardly have been sufficient inflammation of the thyroid to account for it. We conclude, therefore, that this is a suppurating bursa.

CASE 2.—*Foreign Body in the Nose.*—This three-year-old boy is suffering from pain in, and frequent bleeding from the left nostril. He was adopted only three days ago, and his new mother does not know how long the trouble has been present. Respiratory and heart sounds are normal. The odor is not offensive. Introducing a probe into the naris I find a hard substance, which is apparently a foreign body, about an inch from the nostril. A foreign body in the nose that can absorb moisture usually causes a very disagreeable discharge in a short time, while a hard body may not become offensive. For the removal of foreign bodies from the nose I prefer a snare, as the wire takes up little room and usually passes the object easily. I anesthetize the nostril with a solution of cocain, and with this ordinary polypus snare remove the body without difficulty, it being, as you see, a shoe button. It is well after removing an object from a child's nose to explore the cavity to see if there is anything left, as sometimes several objects have been introduced. In this case I find nothing more. No subsequent treatment will be necessary.

CASE 3.—*Deflection of the Nasal Septum.*—This boy has complained of difficulty in breathing through the right nostril for three years past. There is little discharge, and the mucous membrane looks healthy, but there is a marked deflection of the septum to the right, and considerable hypertrophy of the turbinated body on the left. The etiology of deflection of the septum is not well understood, but traumatism and blowing the nose by holding the thumb on one side are generally given as the cause. This boy could not have caused the trouble by blowing his nose, and he claims never to have had an injury of the part. I think both of these among the least of the causes of deflection. It seems to me that the common cause is hypernutrition, with the resultant growth that would occur from congestion. The septum is held firmly by the nasal and ethmoid bones above and by the superior maxillary below. If it grows too rapidly the result is the same as though the ethmoid and maxilla were approximated to each other; in other words, the septum must bend. As deflection continues, thickening occurs, especially at the lower part, and eventually there will be much thickening, so that exostosis will supersede deflection. It is not pleasant to perform the necessary corrective operation on a boy of ten or twelve years of age under cocain, and it is not worth while to try it under a general anesthetic, but when the patient is older I would recommend running a trephine through the lower part, making an opening about one-eighth of an inch in diameter; and possibly a smaller trephine could be passed through at one or two places a little higher up. This should be done, as far as possible, beneath the mucous membrane, avoiding, if practicable, cutting through into the other cavity. I usually cut out with a knife or saw any redundant portions of the exostosis or enchondroma which remain after passing the trephine once. The septum will thus be so reduced in its vertical width that it may be forced to a perpendicular line. Enough tissue must be removed to destroy its resiliency, in order to get a good result. After the operation, an antiseptic tampon of surgeon's lint which has been saturated with a solution of iodoform and boric acid, and allowed to dry, is packed into the naris so as to hold the septum in proper place. This is removed at the end of four or five days, and then a gutta-percha tube is fitted, which is worn four or five weeks, until the wound is entirely healed.

CASE 4.—*Hypertrophic Catarrhal Laryngitis.*—This man, twenty-eight years of age, has found his voice growing weak during the last three years, and he is now aphonic. There is no soreness of the throat, and he is otherwise in perfect health. There is nothing in his history or in the symptoms that would account for aphonia. On laryngoscopic examination I find the vocal cords a good deal thickened. The arytenoids are irregular and thickened, the left enlarged a little more than the right. It is a case of chronic inflammation involving the whole upper part of the larynx. This might result from simple catarrhal laryngitis, or from specific, tubercular, or malignant disease. He claims to have had no specific disease, and there is nothing in the history or former symptoms, or in present appearances, pointing to syphilis. In tubercular laryngitis there is generally less redness than in this case, but usually more swelling, and it is commonly attended by great pain and marked constitutional symptoms. In malignant disease the tumor begins at one point, gradually extends, and for a long time remains unilateral. This, then, must be one of those unusual cases of thickening of the larynx resulting from chronic catarrhal laryngitis. I have seen but two or three such cases during the last twenty-five years. Comparatively strong astringent applications long continued are most likely to benefit this patient. They should be applied every day or two, and should be strong enough to cause discomfort for half an hour to an hour. I shall also order for him moderate doses of iodid of potassium (seven and a half grains after each meal), to be taken possibly for weeks or months, but this is not given with a view to any specific effect.

---

[1] A Clinical Lecture delivered at Rush Medical College, Chicago.

MEDICAL PROGRESS.

The Physical Signs of Pleural Effusions.—In an interesting lecture dealing with the physical signs of pleural effusions, PITRES (*Archives Cliniques de Bordeaux*, 1896, p. 241) points out that displacement of the heart is an habitual symptom of moderate or abundant pleuritic effusions, although it is not observed in adults when the amount of fluid is less than a quart. It occurs when the fluid equals from two to three quarts, and is more pronounced when this is four or five quarts. When the effusion is right-sided the heart is displaced *en masse*, without notable change in its axes, from between two and two and a half inches downward and to the left, so that the apex-beat appears in the fifth or sixth intercostal space outside the left mammillary line. When a moderate effusion occupies the left pleural cavity, the heart tends to assume a vertical position. If the effusion is greater, the heart, retaining its vertical position, is carried *en masse* beyond the right margin of the sternum and is firmly compressed against the anterior wall of the chest. The apex-beat is then visible over several intercostal spaces in a curved line passing from the second or third right chondro-costal articulation to the epigastrium, and reaching to the level of the right nipple, or above. The pulsation in the left mammillary region is, however, due to the aorta and not to the apex, for the heart is not inverted in any case so as to assume an obliquity from left to right with its apex beneath the right nipple. The displacement of the heart as a result of pleural effusions is limited by the tension of the pericardium, whose fibers, firmly attached above to the apex of the chest and below to the central tendon of the diaphragm, submit to a degree of traction corresponding to the depression of the diaphragm caused by the weight of the effusion; in proportion as the diaphragm is depressed the median septum of the mediastinum is made tense. Pleurisy with abundant effusion being always unilateral, it follows that the pericardium tends to the side on which the diaphragm is depressed. If the effusion occupy the right pleural cavity, the right half of the diaphragm is made tense, and the right or auricular portion of the pericardium sustains the traction, and as this portion is normally directed almost vertically, the heart is relatively little displaced to the left. If the effusion occupy the left pleural cavity, the left or ventricular portion of the pericardium tends to become vertical, and as this is normally oblique, the change causes the heart to be displaced toward the right. In both cases the heart is protected from the effects of an exaggeration of the intrathoracic pressure existing within the pleural cavity, distended by fluid. It is by virtue of this protection that the heart continues to beat. Without it the auricles would be restrained and the circulation be interrupted. The cardiovascular accidents and the sudden death which sometimes follow in the course of pleurisy and which have been attributed to displacement of the heart depend really upon multiple and varied causes, but they are not related as cause and effect to the degree of displacement of the heart, for they may occur when the heart is but little if at all displaced, and they may not occur when considerable displacement of the heart exists.

The Treatment of Profound Anemia Due to Puerperal Hemorrhage by Intravenous Injections of Artificial Serum.—MAYGRIER (*L'Obstetrique*, 1896, No. 4, p. 289) has reported an exceedingly interesting case illustrating the life-saving utility of large intravenous injections of artificial serum in the treatment of profound anemia following puerperal hemorrhage. A woman, twenty-four years old, in the eighth month of her third pregnancy, suffered a slight uterine hemorrhage, which was repeated two days afterward. Nine days later, following a long walk, a more copious bleeding ensued and this recurred a number of times in the course of the next few days, until the woman was greatly enfeebled and prostrated. When she came under observation the fetus was found to be dead, with its head occupying the left iliac fossa. The woman was now pale and cold, her pulse rapid and feeble, and the general condition so bad that further examination was desisted from until artificial heat had been applied, stimulants administered, a hypodermic injection of ether given, and ten ounces of artificial serum (consisting of five parts of sodium chlorid and ten of sodium sulphate to one thousand of water) introduced into the subcutaneous tissues. The right shoulder of the fetus was now found presenting on the left side of the mother's pelvis, while the cervix uteri was soft and dilatable. The membranes were ruptured and a foot drawn into the vagina. Further interference had to be suspended owing to the condition of the patient, whose color had assumed a cadaveric aspect, with cyanosis of the lips and a scarcely perceptible pulse. Despite subcutaneous injections of ether, continued applications of heat and inhalations of oxygen, the state of affairs grew worse and death seemed imminent. It was now decided to employ intravenous injections of artificial serum, and two quarts were at once introduced into the left median cephalic vein. The effect was immediate and gratifying. The pulse became appreciable and regular, respiration was resumed with regularity, the face lost its lividity and assumed a pinkish hue and the lips became red. Consciousness returned and the patient expressed her sense of improvement. Forty-five minutes after the injection the amelioration began to recede and in a short time the fetus was expelled. The condition of the woman now grew even worse than it had been before, and a second injection of two quarts of artificial serum was made into the right basilic vein. Again the improvement was remarkable and now the placenta was expelled, together with a large quantity of clotted and liquid blood. This hemorrhage was controlled by an intrauterine injection of hot water, but was sufficient to render the condition of the patient once more precarious. Throughout the night inhalations of oxygen were kept up. A third injection, also of two quarts of fluid, became necessary, with the same happy effects as before. The patient was soon able to sleep and was in every way greatly improved. A slight elevation of temperature necessitated curetting of the uterus, which resulted in the removal of considerable fetid *débris* and the loss of some six ounces of blood. There were no further complications and the case proceeded to permanent recovery.

Application of X-rays to Anatomical Study.—REMY and CONTREMOULIN (*La Semaine Médicale*, 1896, p. 447), by the use of metallic powders in suspension in liquids used as injecting fluids, have shown that the distribution of the vessels can be studied and photographed with extreme accuracy. In the hand and forearm the small arterioles are easily seen, and the large veins can be traced throughout their extent.

THERAPEUTIC NOTES.

A Practical Method of Humanizing Cow's Milk.—The happy results which have followed the use of cow's milk which has been modified so as to conform closely to mother's milk have induced DUFOUR (*Rev. Men. des Malad. de l'Enfance*, September, 1896,) to seek out a practical method for the humanizing of cow's milk in any family. As is well known, cow's milk differs from mother's milk in containing an excess of proteids and salts, while it is deficient in sugar. The amount of fat in the two is essentially equal.

Dufour takes a large graduate which contains about two liters and has at the bottom a spout closed by a cork. Into this he pours the quantity of milk suitable for an infant of the required age for one day. The vessel is tightly covered and set away in some place which is cool in summer but moderately warm in winter. After about four hours the cream will have risen. Through the spout at the bottom one-third of the milk is now drawn off, a quantity of water is added equal to the milk which has been withdrawn, and 35 grams of milk sugar and 1 gram of salt per liter. The whole is mixed by shaking and poured into sterilized bottles. If the infant does not gain weight as fast as it ought, one to two spoonfuls of fresh cream should be added to the day's allowance of milk.

Absorption of Iron in the Intestine.—HOCHHAUS and QUINCKE (*Arch. f. experim. Pathol. u. Pharmakol.* 1897, vol. 37, p. 156) carried on numerous experiments in order to ascertain in what portion of the intestine iron was absorbed. The iron was administered in various forms, both organic and inorganic. The results showed positive absorption in all cases. This took place especially in the duodenum, whose epithelial cells were found to contain fine grains of sulphid of iron. These disappeared if no iron was given for some days. In the stomach and small intestine traces of iron were found only occasionally. In the cecum and the large intestine iron was found in smaller quantities, and in the opinion of the investigators iron is discharged from the economy through these tracts.

Spermatorrhea of Neurasthenics.—This symptom, insignificant in itself, but which occupies an important place in the thoughts of those neurasthenics in whom it is present, has been studied by ST. GOLDSPIEGEL (*Revue de Therap.*, January 1, 1896.). Spermatorrhea is to be attributed to an exaggerated irritability which is often hereditary. It is best treated by electricity, the positive pole being placed over the lumbar cord and the negative pole on the spermatic cord, the penis and the perineum. An application should last two or three minutes, and is to be repeated from four to six times a week during ten weeks. Static electricity may also be applied. Hydrotherapy and bromid of potassium have also given good results.

Dyspepsia Accompanied by Acne.—MITOUR (*Revue de Therap.*, December 15, 1896,) recommends for cases of dyspepsia accompanied by acne, light meals, frequently repeated. The food should be well chewed and of an easily digested character. Bread, spiced meats, preserved fish, pastry, butter, and fatty foods should be avoided. Alcohol and milk are also injurious. Water is the best drink and should be taken sparingly with meals. Medicinal treatment is three-fold; (*a*) to stimulate the secretion of hydrochloric acid there should be given before meals bicarbonate of soda with sulphate of soda and potash in small doses, or ipecac, or condurango; (*b*) to stimulate the muscular action of the stomach the tincture of nux vomica may be given after meals; (*c*) to prevent fermentation naphthol, benzol, beta-naphthol, or salicylate of bismuth are indicated. For constipation with intestinal inflation sulphate of soda and calomel are recommended. In certain cases hydrotherapy, abdominal massage, gastric lavage and electricity have given excellent results.

PLEURISY.

THIS is one of the most frequent of the milder diseases that afflict the human race and is likewise a most distressing malady. In the management of it the resources of the attendant are more especially invoked in the department of those duties which are directed to promptness in restoring his patient to health and in making him comfortable during this process. The subject is handled so concisely and yet so completely and satisfactorily in the article which we publish this week and in the discussion which follows, that we cannot resist calling the special attention of our readers to it. It is valuable; it is practical.

THE CHAMBER OF EMULATION.

JEAN LOUIS PETIT was not more famous as a surgeon than as a teacher. The fame of the Paris School of Medicine, in the last century, was largely due to his personal power as a teacher, and his skill as an organizer. During the period of his incumbency of the position of dean of that school, an event occurred which conveys a lesson that the teachers in our medical colleges would do well to heed. It appears that at one time the professors became very lax in the performance of their duties. They arrived late at the college, the lectures were rapidly delivered, and were the same that had often been heard before. On the conclusion of the lecture the individual professor hastily left the college, and no student had an opportunity to ask a question which would solve a doubt or aid him in his course of study. The students finally became disgusted with the farce and adopted the very sensible resolution that they would no longer attend lectures, but would teach themselves. Accordingly they notified the dean that they would no longer waste their time in the lecture-room, and thereupon they organized a society called the Chamber of Emulation. The plan of instruction devised was that of mutual aid, the senior student especially acting as teachers.

The success of the movement was so great as to alarm the faculty, and Petit undertook to counteract the new departure. At first he endeavored to win the students back by giving fanciful lectures on attractive subjects, as surgical instruments, exhibiting them and explaining their uses and comparative merits. This effort having signally failed, he adopted a method of teaching not unlike that which proved so popular in the Chamber of Emulation. He announced that, instead of giving formal lectures as before, he would propose questions for discussion and the students should have the greatest freedom in debating with him, being allowed to ask and answer questions freely. This proposition was received with great favor, and the students returned to the lecture-room and to their allegiance to the professor. They were only too willing to give up their own organization when the professor consented to take the place of the senior student and both question and be questioned.

This episode in the history of the Paris School of Medicine strikingly illustrates the defects in our system of medical instruction as viewed from the student's standpoint. To him the lecture-room has few attractions when he is studying the technical branches as anatomy, physiology, chemistry, and the principles of medicine, surgery, and obstetrics. And even in studying the practical branches he labors under great disadvantages when the instruction is given only by formal lectures. If he is a graduate of a literary institution he notices a vast difference between the literary and medical colleges in the method of teaching purely technical branches. He learned his Latin, Greek, and mathematics in the class-room of the tutor or professor by questions and answers, but he is now to learn his anatomy, physiology, and chemistry, by listening to a lecturer with whom he rarely if ever exchanges a word. These lectures are by no means always instructive. Too often, as in the Paris School, they are not prepared for the occasion, but are delivered in a perfunctory manner. At the close of his lecture the professor usually hastens from the school as if fearful of having a question asked him.

It is not surprising that in the medical schools which adhere to the old system of instruction in the technical branches by formal lectures, the earnest student finds little positive aid in the discourses which, though often entertaining, are too frequently uninstructive. He soon discovers that he can learn anatomy, chemistry, and physiology, only by close application to text-books, by work in the dissecting room and laboratories, and by the personal instruction which he obtains in the examination room of a competent teacher. To secure this kind of assistance the student is compelled either to employ a private medical teacher and thus pay a large second tuition fee, or he associates himself with other students for mutual improvement by discusssons and examinations, thus creating a "Chamber of Emulation." When he is provided with these aids to study he attends the lectures only for pastime or amusement, or to comply with the rules of the school. At the close of the term he is certified to have attended a full course of lectures. Thus, in due time, he complies with the letter of the rules for graduation and appears before the faculty for examination. No member of the teaching body knows him personally, and he is recognized only by those who recall a face which they have somewhere and at some time seen. He proves to be a remarkably apt scholar in every branch, and even answers the usual "catch" questions by each professor, having been properly "coached" by his preceptor. He receives his diploma and departs and ever holds in grateful remembrance the young teacher, outside the college walls, to whom he is indebted for his medical education.

We commend to the thoughtful consideration of the faculties of our medical schools the incident in the Paris school and the lesson which it enforced upon Petit and his colleagues. The same question which they raised is on the lips of hundreds of students to-day who are beginning their course of study. In their own private circles they ask: Why should not all branches of the medical sciences be taught by personal contact of the student with the living teacher as in the academic course? Why should not a sufficient number of teachers be employed so that the class may be divided into small sections which would bring the teacher into daily personal relations with each student that he would learn his mental traits, his habits of study, the peculiarities of his modes of thought, and thus be able to aid him promptly in all his difficulties by explanations, illustrations, or demonstrations? It is admitted by every practical teacher that this is the true method of teaching any technical branch of science, and our schools can not much longer delay adopting the scheme and making ample provision for enforcing it.

SURGERY OF THE LUNG.

In the year 1710, nearly two centuries ago, Baglivus suggested that cavities in the lung might be successfully treated by operation. During the next century and a half, an occasional operation was performed for the relief of pulmonary affections, but the surgery of the lung was unsystematic and largely experimental until Graux in 1850 reported the results of thirteen operations. All these cases were, however, unsuccessful, and these results combined with other similar failures retarded the progress of pulmonary surgery for another quarter of a century.

A fresh impulse was given to this branch of surgery some fifteen or twenty years ago when numerous successful experiments on animals, where portions of the lung, and even entire lobes, were excised, led to the hope that the same success might follow operations on the human lung. This expectation, however, has not been fully realized. Especially is this true in regard to tubercular processes which would offer a vast field for operative interference were success to follow such treatment. In this class of cases there seems to be but little hope of benefit to be derived from excision of tubercular foci. Reclus, in a most admirable address which he delivered before the French Surgical Congress in 1895, said, "Resection of the lung for tubercular disease seems to me condemned past appeal." This judgment may be somewhat too severe and yet it probably expresses the view of most conservative surgeons on this subject.

The results of simple incision into tubercular cavities have been somewhat more favorable. A number of patients have been benefited by this procedure, and in certain cases this operation seems indicated. A successful termination must be exceptional, however, as the original focus of disease must still remain, and probably other foci also. Reclus reports eight such operations upon an equal number of patients, only two of whom died, while five were improved or cured. He states, however, that all were carefully selected cases. Laufert and Worth have calculated that out of 100 such cases, 5 die at once as the result of operation, 10 die within a fortnight, 15 more inside of a month, 10 are improved, and zero represents the number of recoveries. Paget reports 24 operations, with 9 deaths, 5 recoveries, and 5 improvements.

Operation for pyopneumothorax, as the result of tubercular ulceration, has been performed in a number of patients, in two of whom the opening was successfully closed by suture. The difficulty however of locating the perforation must be great, and at best temporary relief only can be afforded.

The results of operation for growths in the lung are equally disappointing. When carcinoma or sarcoma occurs primarily the growth is in all probability so extensive before the diagnosis can be made that extirpation is impossible. In some cases where the malignant tumor has extended to the pleura and lung from the chest it is possible that extirpation might be successfully accomplished.

In abscess, gangrene, and hydatid cysts, sufficient experience has accumulated to enable us to judge approximately of the risks of operation and of the chances of recovery. The results are becoming more and more favorable and undoubtedly will be still more encouraging as soon as physicians can be convinced that operation is not attended with great risk and that it offers a fair chance for recovery.

The results of operation for pulmonary abscess are certainly full of promise. Thus Fabricant reports 38 cases, with 29 recoveries, and 9 deaths. Reclus reports, out of 23 operations which have been performed within the past ten years, 20 cures and 3 deaths. The old idea that adhesions between the lung and parietal pleura were a requisite for successful operation is happily passing into oblivion. Adhesions are unquestionably of great advantage. When they exist the danger of infecting the pleural-cavity and thus exciting a pyopneumothorax is very slight and the incision into the abscess cavity is a comparatively simple operation. Many successful operations have been performed however where there are no such adhesions, as for example the cases recently reported by Smith and Frederick Treves in the *Lancet*, and by Northrup in the *N. Y. Medical Journal*. If adhesions are absent the operations can be carried out in two stages, at the first, suturing the two pleural layers; at the second, opening the abscess after a delay of a few days. Unfortunately, however, such delay is generally inadmissible. It means death. The abscess must be opened at once. In certain cases the parietal pleura may be sutured to the lung, but generally the patient's condition is such that the operation must be rapidly completed, the pleural cavity being protected as well as possible by sponges and gauze.

In gangrene the mortality without operation is about eighty per cent. In certain cases of diffuse gangrene operation is out of the question, and the case is hopeless. In circumscribed gangrene operation offers to the patient a fair chance of recovery. Excepting a few cases of gangrene occurring in young subjects where the patch is small and near the apex, it is a question whether operation should not be advised as soon as the diagnosis is made in every case of circumscribed gangrene where the general state of the patient or some intercurrent disease does not render all treatment hopeless. As in abscess so in gangrene; the operation, if otherwise indicated, should be performed, adhesions or no adhesions.

Another reason for delay which is sometimes advocated is that operation is not indicated until after the stage of consolidation has passed and deliquescence begun. The latter stage however is generally reached before the diagnosis has been made. Of course the patient may recover without operation, but the dangers of sepsis or the conversion of a circumscribed into a diffuse gangrene more than counterbalances the risk of an operation. These risks are not very great, as may be judged from the statistics of Heydweiller who collected 40 cases treated by operation prior to 1892, with 22 recoveries, 4 improvements, and 14 deaths. The more recent cases of Reclus number 14 operations, 11 of the patients being cured, 1 being improved, and only 2 having died.

In cases of bronchiectasis the results of operation seem to be less hopeful. More than one cavity generally is present. One may be incised and healed but others are left. Reclus reports 12 operations, 8 of which terminated fatally, 4 of the patients being improved, but none cured. Paget reports 5 cases all of whom were improved, but he adds that all were exceptional cases. The conclusion of Truc seems correct: "When the cavity in the lung is the essential lesion, when the symptoms of septic absorbtion dominate the scene, when there is high fever and the patient is shaken by cough and exhausted by profuse expectoration, then without raising vain hopes and simply to alleviate suffering we may have recourse to incision of the lung. Now and again a marked improvement has been noted."

The results of operation for hydatid cysts have been most satisfactory, indeed more so than for any other pulmonary affection. Paget has collected 45 cases thus treated, 37 of the patients being cured, and 6 having died. In this condition operative interference is always indicated.

Andrew J. McCosh, M.D.

ECHOES AND NEWS.

Vacant Professorships in Philadelphia.—The chairs of anatomy, clinical surgery, and genito-urinary surgery are vacant at the Medico-Chirurgical College at Philadelphia. Only the chair of anatomy is salaried. All applications should be addressed to Isaac Ott, Dean.

Control of Tuberculosis in Rome, Italy.—We learn by letter of Dr. McDonald, in the *Boston Med. and Surg. Journal*, that tuberculosis is ranked by the Board of Health of Rome among contagious diseases, and prompt notification of all cases is required. Indeed, almost the identical system of management recently promulgated by the New York Board of Health is in thorough active operation there.

The Davy-Faraday Research Laboratory.—The opening of this public laboratory in London will doubtless mark an epoch in chemical science in Great Britain. It was established by Dr. Ludwig Mond, at a cost of $500,000. Of this, $170,000 was expended in the building and its equipment, and $330,000 invested as an endowment. It is open to persons of either sex and any nationality, who can satisfy the Laboratory Committee that they are qualified to undertake original scientific research in pure or physical chemistry.

A Confusion of Names.—We are informed that some confusion has arisen at Carlsbad (Bohemia) because patients who are accredited merely to "Dr. Kraus" find, on arriving, three Drs. Kraus in active practice, viz.: Dr. J. Kraus, Sr., Dr. Frederick Kraus, and Dr. Oscar Kraus. Dr. J. Kraus, Sr., is no doubt, the physician usually meant, he having been associated with Carlsbad so many years, but whether he be or not, it is evident that confusion can only be avoided by correspondents using the full name of the Dr. Kraus intended.

The Tennessee Centennial Exposition.—The Centennial and International Exposition to celebrate the one hundredth year of Statehood by the citizens of Tennessee will be held in Nashville, and the opening day is fixed for Saturday, May 1, prox. Already the sum of over $500,000 has been subscribed by the citizens of the State, and an additional $130,000 has been appropriated by Congress for a special Government exhibit. A separate and special building for medical and surgical appliances and hygiene will be provided for everything pertaining to these sciences and arts.

The British Army in India Incapacitated by Sexual Disease.—It is reported that out of 73,000 British soldiers now in India only 24,000 are free from a special disease in a more or less severe form. One-half of the whole army is incapacitated for prolonged marching service. Preventive measures against these diseases proved very effective among the Indian forces when medical inspection of the cantonments women was practised. Medical regulation of army prostitutes was abolished some years ago through the influence of the English religious organizations. An appeal has been made to the home government by the Viceroy's Council to reëstablish the former custom.

English View of the Plague in India.—Now that the English people have contributed generously to the relief of the famine-stricken, plague-infested fellow-subjects of the Queen-Empress in India, and thus avoided a possible charge of endeavoring to shirk a duty of charity, they have made the situation the occasion for discussion of that pitiless topic, "the survival of the fittest." The public press is endeavoring to answer the following questions: What part do these periodic famines and great epidemics play in the economy of nature? Are they, everything considered, the unmitigated evil which they appear to be? Was Darwin right or wrong in making these great fatal visitations the basis of his theory of natural selection?

Electricity as a Measure of Temperature.—Prof. Dewar announced before the Royal Institution of London January 22 the results of some recent experiments with liquid oxygen and other low temperature investigations. He explained that the temperature of liquid oxygen is constant at 182° centigrade below zero [295°.6 F. below zero]. This scientist has discovered in electricity a means of measuring such extraordinary degrees of cold. As he explains it there is an electric balance, for instance, between a temperature 100° above freezing and 100° below freezing. The temperature of liquid oxygen is determined by immersing one thermo-electric junction in a substance which is boiling at a known temperature of 182° C. above zero, and another in liquid oxygen itself. The two currents which are produced exactly balance each other.

Dinner of the Long Island Medical Society.—The sixth annual dinner of this society took place at the Montauk Club, Brooklyn, Tuesday evening, February 2d, and proved to be one of the most successful affairs of the kind that the society has yet given. Dr. W. H. Clowminzer, president of the Society, acted as toast-master. "The Long Island Medical Society" was responded to by Dr. Henry T. Hotchkiss, the vice-president, and "The Future of the Society" by Dr. John O. Polak. In response to the toast, "Medical Politics," Dr. Arthur C. Brush, a member of the State legislature, made a speech which was listened to with intense interest by the Society, and his remarks were heartily endorsed by subsequent speakers. Dr. Philip T. Brennan spoke on "Dangers Threatening Our Profession," and Dr. S. J. McNamara on "Any Old Thing." Other interesting remarks were made by Dr. R. J. Morrison, Dr. J. M. Clayland, Dr. A. S. Treadwell, Dr. W. E. Butler, and others.

The Sale of Patent or Proprietary Medicines in New York.—A bill has been introduced in the New York Legislature declaring that no drug, medicine or mixture of drugs, herbs or medicines, commonly known as patent or proprietary medicine, shall be sold, offered or exposed for sale in this State, unless an analysis or formula of the contents thereof has been filed in the office of the State Board of Health, and a certificate issued by such Board that according to the ingredients thereof, as indicated by such analysis or formula, the sale and use of such patent or proprietary medicine for the purpose for which the same is advertised or the purchase thereof solicited will not be dangerous to the public health. Every such analysis or formula filed in the office of the State Board of Health shall be preserved as a record of such board, but shall not be open to public inspection, nor shall the contents thereof be revealed by any member of such board, officer, agent or employe thereof, except for the purpose of a criminal prosecution as provided by this act.

CORRESPONDENCE.

THE OPTICIAN'S BILL BEFORE THE LEGISLATURE.

To the Editor of The Medical News.

Dear Sir: A bill has been introduced in the legislature known as Assembly Bill No. 459, entitled "An Act to regulate the Practice of Optometry in the State of New York," which decrees that the Regents shall appoint a Board of Examiners to examine any person who desires to treat any condition of the eyes requiring glasses, and grant a certificate of proficiency which must be hung in a conspicuous place in the office of the recipient. The opticians who call themselves refracting opticians are behind this measure and contend that the refraction of the eye is no part of medicine, and that physicians have no right to take unto themselves the exclusive privilege of this department.

Every physician must be fully aware of the evil consequences that will of necessity follow the passage of a measure of this kind, as the examination requires simply a knowledge of optics, and is one which any person can prepare himself for in a very short time. The sponsors of this measure claim that they need protection; that they have been fitting glasses for a long time, and that they have a right to continue to do so. In answer we say, that the time was, and not so long ago, when the pulling of teeth, blood-letting, and many of the present functions of the physician or those having a medical education, were in the hands of the barbers; but increasing education has demonstrated that in order to protect the public, medical privileges, of which the fitting of glasses is one, can be safely entrusted only to those, who, by careful medical training, are capable of discriminating between health and disease.

The present standard of medical education is higher in the State of New York than anywhere in the United States, and we urge the members of the profession to keep it so. If every physician who reads this statement will write to his or her representatives in the Senate and Assembly, protesting against the passage of Assembly Bill No. 459 in any form which obviates a medical education as something which would be extremely dangerous to the public, the defeat of this measure is assured.

The Committee on Legislation will be happy to furnish names of representatives, or any desired information.

Signed,
D. B. St. John Roosa,
Egbert H. Grandin,
Charles E. Nammack,
William R. Pryor,
Frank Van Fleet, Chairman.

New York,

OUR PHILADELPHIA LETTER.

[From our Special Correspondent.]

MEETING OF THE COLLEGE OF PHYSICIANS—DISCUSSION OF THE RELATION OF NERVOUS DISORDERS IN WOMEN TO PELVIC DISEASE, BY DRS. HIRST, MONTGOMERY, WEIR MITCHELL, MILLS, DERCUM, SINKLER, ANDERS, SOLIS-COHEN, AND OTHERS—MEMOIR OF DR. WILLIAM HUNT.

February 6, 1897.

At a stated meeting of the College of Physicians, held on February 4th, Dr. Thomas G. Morton read a memoir of Dr. William Hunt. Letters quoted by Dr. Morton from Oliver Wendell Holmes to Dr. Hunt, who attended Dr. Holmes' son while suffering from wounds received in the war of the Rebellion, as well as the correspondence between Dr. D. Hayes Agnew and Dr. Hunt in regard to the latter's defense of the methods of the American surgeons in their treatment of President Garfield against the attacks made by Esmarch and other continental authorities, rendered the memorial peculiarly interesting.

The main business of the meeting—the discussion of the "Relation of Nervous Disorders in Women to Pelvic Disease"—was opened by Dr. Barton C. Hirst, who quoted cases disproving the fallacy of always regarding pelvic disease as a causal factor in such disordered states as hysteria, hystero-epilepsy, and the like. In a number of patients coming under his notice, in whom a diagnosis of uterine or ovarian disease had been made to account for the nervous condition, examination had shown the uterus and appendages to be, in some of the cases, absolutely normal, and in others rudimentary. Moreover, sustaining and developmental treatment, addressed to the mind and body, without reference to the possibility of pelvic disorder, had, in the vast majority of cases, proved successful. Dr. E. E. Montgomery, continuing the discussion from the gynecologist's standpoint, said that while deprecating the indiscriminate ablation of the ovaries or uterus, there were cases of actual disease of these organs augmenting or exciting a mental or nervous disorder which their removal would greatly ameliorate. The views of Drs. Shoemaker and Noble practically coincided with those already expressed.

Dr. S. Weir Mitchell said that severe shock of almost any kind had, in his experience, been as beneficial in temporarily improving the mental and nervous condition of such states as those under consideration as had ever ovariotomy or kindred operations. He had never seen a case of epilepsy benefited by operation of this kind, and premature stoppage of the menstrual function had singularly failed as a curative measure in hysterical and mental disorders.

Dr. F. X. Dercum argued that if such trivial lesions as a slight perineal tear and inflammation of the ovaries were responsible for such conditions as hysteria, hystero-epilepsy, etc., much more marked should be the nervous symptoms caused by malignant disease of the genital tract. In cancer of the uterus, however, nervous symptoms such as those under discussion were rarely, if ever, met. Of the so-called hysterical stigmata, he mentioned ovarian tenderness, but to condemn the name, and to substitute inguinal tenderness as a better term. This tenderness he believed to be superficially located in the abdominal wall. For, by fixing the point of most exquisite pain externally with the index finger of the right hand and, *per vaginam*, bringing the same finger of the left hand directly beneath this locality, the two could be approximated, the one directly over the other, with only the thickness of the abdominal parietes intervening. Pressure now at this point produces symptoms identical in every respect with those consequent upon so-called ovarian pressure.

Dr. C. K. Mills believed hysterics, hystero-epilepsy, and insanity to be somatic conditions, whose origin was entirely independent of pelvic disease. Therefore he could not see how the removal of any pelvic organ or disease could have a *curative* effect on these conditions. Yet, if any of these viscera were diseased, their remedy should constitute an integral part of the rational and successful treatment, for by so doing the factor most concerned in augmenting the nervous condition might possibly be eliminated. Speaking of the benefit to be derived in mental unbalancing from ovariotomy, he believed the benefit to be due as much to the shock of the operation as to any curative effects accruing from the procedure.

Dr. Whorton Sinkler said that he had seen a severe case of melancholia markedly benefited temporarily by the severe shock sustained in falling forcibly against a marble mantel, causing a scalp wound of considerable extent, the shock of the fall clearing up the mental condition at once, though for a short time.

Dr. J. M. Anders, taking up the discussion from the standpoint of general medicine, mentioned tachycardia occurring during menstruation, various neuroses of the stomach, and a cough due to reflex bronchial stimulation or congestion as some of the nervous disorders connected with or excited by pelvic disease.

As bearing upon the subject under discussion, Dr. L. W. Steinbach and Dr. S. Solis-Cohen reported a case of kleptomania in association with uterine and rectal disease. The case is one of interest from the notoriety given to it by the secular press, as well as from the standpoint of medical jurisprudence, as the patient was legally prosecuted in England, and pleading guilty to the charge of larceny, was sentenced to imprisonment, but was released upon medical testimony submitted in her defense. The patient's history is briefly as follows: Mrs. C., aged thirty-four, has been married eleven years. She had one child ten years ago and no other pregnancy. During pregnancy she suffered much from hemorrhoids, and was operated upon, and since then has been subject to prolapse of the rectum, at times causing much distress. Previous to fifteen months ago she had suffered little from dysmenorrhea. About that time, following exposure during menstruation, the flow ceased and the patient was confined to bed for some days with headache and feverish symptoms. Since then there has been no real menstrual flow; there was more or less offensive discharge at irregular intervals, and after two or three months a slight watery discharge, at what should have been the menstrual period. For some days preceding this there has been considerable pain in the back and abdomen. The patient showed great nervous irritability and excitement. Inquiry into the patient's life showed that she had ever been "on the go," her day being one of excitement rather than mental occupation. The cheeks are constantly flushed. The left face is moved less than the right, the difference being easily observed; the eyes are roving and restless. In London (the husband states) she heard voices and would go to the door to listen. Later these were also heard at night. She was born with some foot trouble, walked at five years, and wore irons. The heart and lungs were normal, as was the urine. Vaginal examination by Dr. Steinbach showed that the uterus was hypertrophied to one and a half times its normal size; the mucous membrane was irregularly roughened, and bled on the slightest touch by the sound. The cervix had a bilateral laceration, more extensive on the left side. The tear was well cicatrized. The rectum was found to be fissured below, ulcerated above. There were evidences of former ulcers that had cicatrized, and several large hemorrhoids, which bled freely.

Later, under ether, the sphincter ani was dilated, the the fissures cauterized with a Paquelin thermo-cautery, the ulcers treated in the same manner, and the hemorrhoids clamped and cauterized. The uterus was curetted and then the trachelorrhaphy performed by denudation of the cicatricial tissue and suturing with silkworm-gut. The medical treatment of the case consisted in rest, nourishment, and massage. Since the operation she has menstruated twice, four weeks apart, and normal in amount and character. Within two weeks she has left Philadelphia for her home, apparently recovered physically, with her mental condition of such a character as to furnish some grounds, at least, for the hope of complete recovery. Dr. S. Weir Mitchell, who was called in consultation on the case, gave the opinion, which I quote in the hope that it may furnish food for reflection on the part of those who judge too hastily, without the full knowl- of the facts, in cases of just such a character as this.

"After the most careful study of the evidence in the case of Mrs. C——, and of the opinions of the English experts, also from a full knowledge of her case from personal examination of her condition while in this city, I have reached the following conclusions: (1) That Mrs. C——, when arrested and for a long time before, was suffering from a condition described by alienists as kleptomania. It is my carefully considered belief that when she took articles from others she was not then in a state to be aware of the moral nature of her guilt, or to recognize the almost certain consequences of repeated and often careless thefts. (2) I believe the basis of her mental disease to have been hysterical, and that it was largely brought about by long neglected disease of the rectum and uterus. This has now been skilfully cared for, and it is my hope and belief that the results of the operations performed will aid in the cure of the mental malady which the condition described had a large share in bringing about. (3) I do not think that Mrs. C—— was morally responsible for her acts during her stay in Europe, or for some time before that period. As to this I am at one with the English alienists, and believe the Home Secretary to have acted with ample proof when he released Mrs. C—— as insane."

OUR PARIS LETTER.

[From our Special Correspondent.]

PASTEUR'S TOMB—PROPHYLAXIS IN CHILDREN'S HOSPITALS—PRIZE WINNERS OF THE FRENCH ACADEMY OF MEDICINE FOR 1896—A SUGGESTION FOR AMERICAN SURGEONS.

Paris, January 16, 1897.

Pasteur's tomb at the Institute Pasteur is now open to visitors on the first and third Saturdays of each month, to-day being the first that the medical visitor, who did not care to be disturbed by the curious crowd that flocked to the opening, might make his visit in peace. The mausoleum is worthy of the great man whose mortal remains rest in it. The Minister of Public Instruction, in his address at the formal opening, on December 26, when the sarcophagus was transferred from the chapel in Notre Dame, where it had reposed for over a year, said that in other times pilgrimages to the tombs of great benefactors of the race had drawn crowds of devotees for years, sometimes centuries, after their death. To this tomb of the humble scientist, whose life had been spent so faithfully and so fruitfully for the benefit of his fellows, he hoped that during succeeding years the devotees of science would come and would there appreciate the greatness of the master's work.

The tomb is a marvel of artistic beauty, and is well worth a visit merely as a work of art. The architect was Charles Louis Girault, who has been chosen as one of two to make the plans for the buildings for the Universal Exposition to be held in Paris in 1900. The model that suggested the general plan of the mausoleum is the Galla Placidia at Ravenna, that wonderful work of Byzantine art that has attracted so much attention for some fourteen centuries. The cartoons for the interior decoration are from the hands of Luc Olivier Merson, who has just been engaged to design the decorations for the new Opera Comique here in Paris, and who shares with Puvis de Chavannes the honor of being the greatest decorative artist in France. The decorations are in mosaic by Auguste Gilbert Martin, who is eminently worthy of his collaborators.

The mural and tectal decorations are of varying greens on a groundwork of gold, that make a strikingly rich and pleasing contrast. Pasteur's work on wine and beer and silk worms give a very aptly symbolic meaning to the profuse employment of the beautiful shapes and the varying shades of green of the vine, the hop and the mulberry leaf, and this has been taken advantage of with wondrous effect. In the dome of the little Greek cross-shaped mausoleum are four figures of Faith, Hope, Charity and Science. They are sisters who are said not always to live in harmony, and if the youngest of the group does not find herself regarded askance by her older sisters here, especially by the eldest, Faith, it is that in some wonderful way in the life of the man whose ashes they now guard, devotion to one did not lead to neglect of the others, for biological studies, that are said usually lead away from old-established beliefs almost inevitably, did not, in his case, disturb the even tenor of the old ideas as they had come to him from a lowly but ever well-beloved father and mother.

Abroad one cannot help but think that a cloud still hangs over Pasteur's fame because of the lingering doubts still so prevalent as to the success of his treatment for rabies, though none, absolutely none of them, are left here in France. The other wonderful work of his life lies hidden somewhat behind that cloud, and its suggestiveness for other workers along collateral lines, sometimes at great distances from his discoveries, is lost sight of. It takes the beautiful tribute of a man like Sir Joseph Lister to make some of us carping foreigners realize how much Pasteur's work means to modern scientific medicine and surgery.

Lister attended the exercises as the representative of the British Scientific Society, and his tribute was that of one who felt how much of the work that he had done himself had owed its suggestion to that of another, and that other the man he was happy to be able to honor by bringing him the tribute of distant brothers.

In marble, beautifully veined in irregular dark lines, in red letters that mark the abrupt, incongruous, and usually too prominent effect of an inscription, are the scanty words that chronicle a life work rich in bounty for mankind, and that form some of the most brilliant pages in modern science.

They are just now deeply interested in France in the question of the prophylaxis in children's hospitals of what history sheets are prone to glibly call the usual diseases of childhood. All of them contagious, and to a great extent preventable by the adoption of proper hygienic measures, it has been the custom to make too little of some that are usually mild, and to consider almost that it was as well for an individual to have them when young and be done with them. More and more are the unsuspected after-effects of contagious diseases in childhood encroaching on the domain of etiological pathology in the matter of degenerations, both nervous and visceral, in later life. Besides this, some of these diseases have a distinct mortality of their own that is alarming enough when the statistics are presented. Whooping-cough is just now occupying attention in this line. In private practice in France the mortality ranges from six to ten per cent.; in hospital practice it is from twenty to twenty-eight per cent. Complications of the disease almost inevitably ensue in at least one-half the cases of the children of the poor, whose constitutions are undermined by other diseases when the infection of whooping-cough takes hold in the hospitals. Yet a series of well authenticated observations show that the limit of the contagiousness of the disease is always the apartment of the patient, the presence of a corridor between infected and uninfected wards being sufficient to protect the uninfected if reasonable thought and not very special additional precautions be taken.

French children's hospitals are about to take measures to segregate as far as possible all cases, even of minor infections, and prevent their spreading beyond original cases.

Just before Christmas the French Academy of Medicine announced its prize winners for the year 1896. Among a dozen of foreigners who received mention was one American. One is tempted to wonder if our enterprising countrymen would not be heard from more frequently in some of the competitions for the valuable prizes given for practical medical and surgical subjects if the conditions of competition were known. Here, for instance, are two competitions where Americans would not be handicapped in the race; the Laborie prize of 5,000 francs annually to the author of the work which will have caused the most notable advance in surgery during the year; the Argenteuil prize (sexennial) to be awarded next in 1899—value, 6,800 francs—to the inventor of the most noteworthy improvement in the matter of curing or ameliorating strictures of the urethra, or to the author of the best work on the treatment of other diseases of the urinary passages. In neither competition are translations required.

TRANSACTIONS OF FOREIGN SOCIETIES.

Paris.

ULCERATIVE STOMATITIS CAUSED BY ANTIPYRIN—SUCCESSFUL REMOVAL OF THE ENTIRE BLADDER—SURGICAL TREATMENT OF DEAFNESS—SOME SUCCESSFUL NEURECTOMIES—A NEW THEORY OF CICATRIZATION IN THE CORNEA—PENETRATING WOUND OF THE ABDOMEN CAUSED BY A BLANK CARTRIDGE—INDICATIONS FOR OPERATION IN RENAL TUBERCULOSIS—DEATH AFTER OPERATION IN EXOPHTHALMIC GOITER.

AT a meeting of the Therapeutic Society, held December 23, 1896, **DALCHE** reported a case of *ulcerative stomatitis due to the absorption of antipyrin.* The patient was a gouty individual of sixty-five years, who had often taken antipyrin without bad effects. One day, after a dose of thirty grains, an aphthous stomatitis appeared. An injection of fifteen grains of the same drug produced an ulcerative stomatitis with a purpural eruption of the skin. The urine contained an excess of phosphates and urates, but no albumin. A few days later it contained .3 per cent. of sugar. The cause of the intoxication by antipyrin could not therefore be explained by renal insufficiency.

At a session of the Academy of Medicine, held December 29, 1896, **GARNAULT** said that *chronic deafness may be treated by excision of the tympanic membrane,* ablation of the malleus and incus, and mobilization or extraction of the stapes, by means of operation through the mastoid process. This operation is justifiable when one has to deal with deaf persons, in whom it may be asserted, or at any rate assumed as highly probable, that the cause of the deafness lies solely or principally in lesions of the apparatus of transmission. Rinne's method of exploration nowadays permits the surgeon to distinguish with absolute certainty between cases in which operation should and should not be performed. In his opinion all patients by whom the vibrations of a tuning-fork are perceived more distinctly through the skull than through the air should be operated upon.

January 5th, **TUFFIER** described an operation performed upon a man aged forty, in whom a tumor occupied the entire left wall of the bladder and the mucous membrane of its fundus without infiltration of the lymphatic glands. The entire bladder was removed. Phlebitis of the right leg followed the operation. The ureters were catheterized for seven days, and then a hypogastric siphon tube was employed. The patient left his bed in seven weeks, and went to work in ten weeks, using a hypogastric receptacle for the urine. Upon microscopic examination the wall of the bladder was seen to be infiltrated by an alveolar epithelioma of an unusual type.

At the session held January 19th, **PEAN** presented a man, aged twenty-five, affected with multiple neuromata, upon whom he had practiced *resection of considerable portions of the median and ulnar nerves.* This operation was followed naturally by a paralysis, both motor and sensory, of the tissues supplied by these nerves. This paralysis gradually disappeared, until the patient was able to use his hand perfectly, except for delicate motions.

Ten months after operation all the neuromata which existed in the forearm and in the subclavicular region had disappeared.

Chipault showed a patient upon whom he had performed resection within the dura mater of the posterior root of the eighth right cervical nerve, for an obstinate neuralgia exactly corresponding to the distribution of this nerve. From the instant the patient recovered from the effects of the chloroform up to the time of his presentation to the Academy—a period of two years—there had been no return of the pain. The area of distribution of the nerve was hyperesthetic for about twenty-four hours. Aside from this there was neither motor nor sensory disturbance.

At the session of the Academy of Sciences held December 28, 1896, **Ranvier** advanced a new theory in respect to the *cicatrization of wounds in the cornea*, based upon experiments made upon living rabbits. As is well known, the cornea consists of an anterior epithelium, a layer of connective tissue without blood vessels, and behind, a single line of endothelial cells resting upon the vitreous membrane. The anterior epithelium is composed of several layers of cells, the deeper ones being cylindrical, the middle cubical, and the superficial flattened. Some of the deeper cells, known as foot-cells, are softer, and are filled to a greater extent with a nutritive matter than those which surround them, and by which they are, therefore, compressed. The corneæ were incised by Ranvier, and the wounds examined after various intervals. After twenty-four hours a wound was found to be lined throughout with epithelial cells, but the epithelium on each side of the wound, far from showing any signs of nutritive hyperactivity, as might be expected in accordance with the generally accepted theory, was markedly thinner than usual, and also changed in structure. The middle layer of cubical epithelium had partly disappeared, while the deep columnar cells had broadened out, and none of the highly nutritive cells before spoken of were to be seen. The process is apparently a mechanical one. The deep cells, like soft elastic balls, are packed together at a certain tension. If a hole is cut at one spot the balls escape, of course. Ranvier saw no traces of karyokinesis or direct cell division, but even if a few cells underwent such division this would not in the least detract from the importance of the facts above referred to.

At the Surgical Society, January 6th, **Michaux** reported upon a *penetrating wound of the abdomen, produced by the explosion of a blank cartridge*. The accident was caused by the careless handling of a Lebel rifle, the muzzle of the gun being very close to the skin at the time it went off. The result was a fracture of the left iliac crest and a perforating wound of the abdomen. The wound was enlarged, and numerous pieces of pasteboard and cloth were removed from the muscular layers, but a careful examination showed no trace of a lesion of the intestine. The laceration of the peritoneum was closed, and the external wound drained. No abdominal symptoms resulted, but the compound fracture of the ilium delayed recovery for two months.

Robert stated that experiments made by army surgeons show that pasteboard wads in blank cartridges are projected with a rapidity of about 700 meters per second, and that the expansion of the gases is considerable. With a blank cartridge a person can blow a ragged hole in a pine board similar to that resulting from the use of dynamite. The danger of wounds of this description is very great at a distance less than fifty centimeters, and blank cartridges ought never to be fired at a distance less than two meters.

At the session of January 13th, **Tuffier** expressed the opinion that *tuberculosis of the kidney is often primary and unilateral*, and, therefore, amenable to operation. If untreated, renal tuberculosis may give rise to certain accidents, to prevent which, as well as to remove a primary tubercular lesion, is the object of operation. The accidents referred to are hematuria, pain and infection, or intoxication.

Hematuria becomes an indication for operative interference only in those cases in which by its persistence or gravity it threatens the life of the patient. Tuffier had two cases of this character. In one of them the kidney was removed, while in the other it was merely incised. In both instances the hematuria was permanently relieved. In three cases under his observation pain was so persistent and severe that primary nephrectomy was performed. In two of these cases recovery was apparently perfect; in the other, a tubercular ulceration was afterwards seen in the bladder about the orifice of the ureter of the affected side. A most unusual case occurred in a physician who suffered for years with a tuberculous pyelonephritis and cystitis. Rectal examination showed a painful mass in the left part of the bladder. A cystotomy was performed, and an immense cyst was removed from the left ureter.

Accidents of infection or intoxication give the most frequent indication for operation. Such patients have an irregular fever, with evening rises, or digestive disturbances with progressive emaciation and cachexia, sometimes accompanied by pain in the region of the kidney and sometimes not, and either with or without pyuria. Tuffier operated nine times to relieve these symptoms of infection. The operations were five nephrotomies, two primary nephrectomies—one partial and one total, and two secondary nephrectomies. One of the nephrotomies died from the operation. The primary nephrectomies both recovered. Prognosis in secondary nephrectomy is very grave, and if indicated this operation should be performed with as little delay as possible, in order to remove from the body the focus of infection.

Galliard reported a case of *acute sygmoiditis* to the Medical Society of the Hospitals, January 8th. The patient was a woman, aged twenty-eight, who had had no movement of the bowels for a week, and had vomited for two days. Examination showed a large oval non-fluctuating tender tumor in the left iliac fossa. The pelvic organs were normal. The temperature was 39.1, C. Gas passed frequently *per anum*. A purgative was administered, the bowels moved, and the fever subsided. Although no pus was evacuated the iliac tumor rapidly decreased in size, and was no larger than a walnut at the time the patient left the hospital.

January 15th **Debove** reported a *fatal case of thyroidectomy performed in Graves' disease.* The operation was without any complication whatever. Only the right lobe of the gland was removed. For several hours the patient presented no unusual symptoms. About 6 o'clock of the day of operation there was slight dyspnea, which rapidly became worse, and was followed by agitation, delirium, and coma, death occurring the same night. Nothing was found at autopsy to explain this sudden death.

Marie thought that a distinction should be made in exophthalmic goiter between those cases which begin with tachycardia and develop afterward the thyroid enlargement and those cases in which the goiter precedes the palpitation by possibly fifteen or twenty years. His study of statistics (which, unfortunately, are often incomplete on this point) has led him to believe that most of the fatal operative cases belong in the former class, and most of the recoveries in the latter. The results of treatment by thyroid extracts correspond in this respect to the results of operation, for this treatment is useless or injurious in the true exophthalmic goiter, but is beneficial in those cases of goiter which have taken on symptoms of the exophthalmic type.

Vienna.

CURIOUS THICKENING OF THE VEINS—AMBULATORY TREATMENT OF FRACTURES OF THE FEMUR—DIAGNOSTIC WORTH OF HYPERLEUCOCYTOSIS OCCURRING DURING DIGESTION.

At the session of the Imperio-Royal Medical Society held December 18, 1896, **Schlesinger** described a curious thickening of the superficial veins which he observed in the extremities of two patients. The veins were very stiff and scarcely compressible. There were no subjective symptoms. One of the cases came to autopsy, and there was found an extensive phlebosclerosis without any sclerotic change in the arteries. He had observed several similar cases in which the stiffness of the veins was only temporary. In two of these the condition could be brought about by the application of ice or electricity, and relieved by the application of heat. One of these veins was removed. It was stiff at the time, but collapsed before the operation was finished, and neither by macroscopic nor microscopic examination could anything unusual be made out in its walls.

At the session of January 8th **Haudek** presented a case of fracture of the femur treated by him in an ambulatory apparatus, as recommended by Hessing. The principle of this and other forms of apparatus is the production of extension and counter-extension, together with fixation of the fragments. A plaster of Paris bandage fulfils better than Hessing's apparatus the last mentioned requirement, but with the disadvantage that it often produces pressure necroses and stiffness of the joint. Hence, he prefers the other apparatus, which, if carefully moulded to fit the limb, gives entire satisfaction. The advantages of ambulatory treatment are a reduction of the time of convalescence by reason of a rapid formation of callus (the tissues being better nourished through the blood), an avoidance of atrophies, an improvement of the general health, and a prevention of a long rest in bed, which is especially dangerous for old people and drinkers.

Schur found as the result of investigations carried on by himself and Burian that in most cases a hyperleucocytosis accompanies digestion, but that the time of its commencement and continuance vary greatly. He, therefore, concludes that on account of its slight degree and inconstancy, and occasional absence altogether, that it has no diagnostic value as an indication of the state of the digestive faculties.

SOCIETY PROCEEDINGS.

MEDICAL SOCIETY OF THE COUNTY OF NEW YORK.

Stated Meeting held January 25, 1897.

The President, Dr. Landon Carter Gray, in the Chair.

R. C. M. Page, M.D., read a paper on

PLEURISY, ITS DIAGNOSIS AND TREATMENT. (SEE PAGE 198.)

DISCUSSION.

Dr. E. G. Janeway said that the etiology of the disease is of great interest. It is not uncommon to meet with an explanation of the cause of the disease in cases where septic processes exist in other parts of the body. He had seen several such cases, in one of which there was a cellulitis of the arm. Pneumonia developed, followed by a rapid accumulation of fluid in the pleural cavity, which was feared to be an empyema, because of the coexistence of the cellulitis. Whispered resonance was absent, which, under these circumstances, usually means pus in the chest, but on aspiration the case was found to be one of serous pleurisy. For diagnostic purposes it is better to employ an aspirating needle rather than a hypodermic needle, and the fluid should be drawn off. He had frequently drawn off as much as twenty ounces of serum, which contained very little fibrin and no microörganisms. He thought the accepted ideas as to the etiology were not always satisfactory, and did not believe there was such a thing as rheumatic pleurisy, although pleurisy is often associated with rheumatism, and at times with pericarditis. Rheumatic pneumonia is simply a double pleurisy. In such cases he has introduced a needle into the top of the lungs, and found fluid in most of them.

Another diagnostic point is the differentiation between pneumonia and pleurisy. In pneumonia of the lower lobe there is always a line of flat dulness; in pleurisy a line is also found, its highest point being in the axilla, lower in front and lower behind. Of course if there are adhesions, the curved line will not come out so completely. A change of position will also make a difference. In pneumonia associated with a compressed bronchus, the differentiation is not difficult. Two methods can be employed, one of which is mensuration, which is too often neglected in the diagnosis of chest diseases. With a pleurisy filling one side of the chest, there will be increased mensuration on that side. With pneumonia and a compressed bronchus there is rarely an increased mensuration. The second test is the heart displacement, which is of great importance. In pneumonia the heart will be in a normal position; in pleurisy, it will be displaced. Attention to these points will save a good deal of time and trouble, and will sometimes prevent the introduction of needles into an adherent lung. Mensuration should always be employed before aspiration. In regard to voice sounds, in an obstructed lung there will be an absence of whisper resonance; in pleurisy with effusion, the voice will sound distant, and in empyema there may be a total absence of voice.

As regards the use of blisters, he thought that they are not infrequently of service. He had seen blisters applied in the first stage that were apparently followed by almost instantaneous cessation of pain. The use of salicylate of soda is followed by good results in the rheumatic type of cases, improvement occurring rapidly, from which fact it might be inferred that the pleurisy is rheumatic in origin. He advocated dry diet, allowing fluid equal to two-thirds of the amount of urine passed by the patient in twenty-four hours. He uses iodid of potassium in some cases, but has found that patients with much fever do not stand this treatment well, in which case it must be stopped and tried later on.

Rules regarding when to aspirate are variable, and at times a good deal depends upon the patient. Some will not submit to aspiration, and then it must be postponed until their frame of mind changes. Aspiration should always be employed when there is dyspnea, which renders the patient uncomfortable, never mind at what stage of the disease. In regard to the point at which to aspirate, he preferred the fifth or sixth interspace in the axilla, or between the eight or ninth ribs in the scapula line, and never higher, except in those very rare eases of upper lobe pleurisy. He had met with several instances where the pleurisy was sacculated in the upper lobe, and there was no fluid below. Such cases are most difficult of diagnosis, and their nature could be determined only by aspiration or exploratory puncture with a hypodermic syringe. In regard to the effect of aspiration, he thought that even the withdrawal of a hypodermic syringeful of fluid will relieve the pleurisy, and that not only does it do good at the time, but afterward. He thought this was due to the fact that the pleura is actually punctured by the aspirating needle, allowing the fluid to drain into the subpleural tissue whence it is absorbed.

In tuberculous pleurisy, he had tried a plan of treatment which had met with success in two cases. He had injected creosote in alcohol into the pleural cavity with good results. In a third case, empyema had followed, which was probably due to some infection. In cases of pus in the pleural cavity everybody agrees that the best thing to do is to incise and drain. It is a waste of time to aspirate in such cases.

DR. H. P. LOOMIS said the subject of the etiology is a very important one, and one in which he was especially interested, as he had been making a study of it for the last five or six years. As his observations had been made in the autopsy room, his conclusions were based upon facts and not upon theories, and his opinions were confirmed by investigations of foreign observers.

The idea of the tuberculous origin of the disease had not been borne out by his studies. Of course, there are cases in which pleurisy has been followed by tuberculosis, but these are not tuberculous in the beginning. Within a day or two he had gone over a list of 300 autopsies made under his personal supervision during the last year or two, of which notes had been carefully taken, and especially so in regard to the condition of the pleural cavity and lungs. Of these 300 cases twenty-seven showed an acute pleurisy, of which only three were tuberculous. Another set of ten cases showed subacute pleurisy, and two of these had advanced tuberculosis, which had apparently preceded the pleurisy. Another interesting point was that when pleurisy develops in cases of advanced phthisis, it seemingly causes the latter disease to come to a standstill.

Regarding the presence of fluid in the chest in pleurisy preventing the formation of adhesions, he had tried injecting sterile fluid into the chest for this purpose, but had never been able to find any which would remain there without being absorbed. In his observations over fifty per cent. of all cases of pleurisy showed adhesions, indicating, in some instances, a localized pleurisy, from which the patient recovered,

DR. FRANCIS DELAFIELD said that the relationship between tuberculosis and pleurisy was something which had been very much written and talked about during the last few years, so much so that some conclusion should be arrived at. To do this it was first necessary to determine what is meant by "tuberculous inflammation." In his opinion, this was an inflammation in which tubercle bacilli were present in the inflamed tissues and in the exudation. He did not think a pleurisy could be called "tuberculous" unless tubercle bacilli were found in the pleura and in the exudate.

There are four different conditions under which pleurisy may be found. In the first place, there may be a localized tubercular pleurisy without tubercle bacilli in the lungs. In the second place, there are patients with tuberculous lungs and tuberculous pleurisy. Thirdly, there are patients with tuberculous lungs and a pleurisy that is not tuberculous—in which no tubercle bacilli can be found in the pleura or in the exudate; in other words, a simple pleurisy occurring in a person afflicted with tuberculosis. And lastly, there are ordinary cases of pleurisy with effusion, acute or subacute.

In regard to the treatment of pleurisy with effusion, the speaker said that in the early years of his experience he had followed the routine plan, consisting of the repeated application of blisters to the chest, and the administration of iodid of potassium and digitalis, and waited for the fluid to be absorbed. If fluctuation were present the fluid was drawn off with the trocar. He first gave up the blisters, then he began to give less and less drugs, and then he began to aspirate earlier and earlier, until, within the last four years, he had reached the conclusion that aspiration was *the* treatment for pleurisy, and was to be employed not merely to draw off the fluid, but to cure the disease in the shortest space of time. Now his ordinary routine treatment is to aspirate for the cure of the pleurisy in all cases in which there is an appreciable amount of fluid in the chest cavity, it mattered not whether the case was one of acute or subacute pleurisy, or whether or not the patient was uncomfortable. As to the amount of fluid to be drawn off, this varies with the amount present; if there is not much he draws off all he can; if the chest is distended with fluid he draws off a moderate quantity. The largest quantity he had ever drawn off was 3,700 cc., and the smallest 90 cc. Ordinarily only one aspiration is required, and a week later the patient is generally well enough to get about. He thought that any one who follows this method of treatment will be surprised to find how much the duration of the disease is shortened. He thought that most cases of simple pleurisy with effusion get well in the long run—sometimes in two or three weeks, sometimes in two or three months; but it makes a great deal of difference to most people whether they get well in two weeks or in two months, and for this reason he considered the treatment of pleurisy by aspiration to be the best, and therefore recommended it highly.

Dr. J. S. Winters said in regard to whispered resonance, that it seemed to him that this depends largely upon the amount of fluid present between the lung and the chest wall. In simple pleurisy with effusion, which has lasted for several weeks, resonance is absent, as in cases of empyema. The reason why whispered resonance is almost invariably absent in cases of empyema is because there is extensive thickening of the pleura, and it is absent in some cases of pleurisy with effusion for the same reason. He said that he was very glad to hear the remarks of Dr. Delafield with regard to aspiration being looked upon as a means of curing pleurisy with effusion. The fluid in these cases usually undergoes absorption, which lasts week after week and month after month, while the physician waits for it to disappear; whereas a permanent and early cure can be effected by aspiration. The withdrawal of a large amount of fluid, he thought, is apt to do harm if there is much effusion, while the withdrawal of a comparatively small amount stimulates absorption, and this may be repeated many times with impunity. He was of the opinion that much harm has been done by neglecting this simple and harmless procedure. He saw no reason why a case of simple effusion should not be incised and drained if several aspirations fail to relieve the disease.

In his experience he had found that in cases of serous effusion in children absorption took place rapidly (in from one to four weeks) without operative interference.

Dr. Beverley Robinson said that it was difficult to add anything to the discussion, as all the important points had been so thoroughly covered. He could only confirm what other speakers had said. He was very happy to hear Dr. Delafield speak in such decided terms of what he had personally long believed to be the proper treatment of pleurisy. His internes at St. Luke's Hospital could bear out his statement that for the last ten or fifteen years he had aspirated whenever there was fluid in the chest. He thought this should be the rule in hospital practice, and in private practice, too, if possible. However, there were certain reasons, which were known to his hearers and which needed no further mention, connected with private practice which made it sometimes impossible to treat cases as one would in a hospital. He was of the opinion that aspiration of the chest does no harm, and almost invariably does good. In his personal experience he had never seen a case in which aspiration, properly performed, had done harm to the patient, and many times in the *post-mortem* room he had regretted that he had not aspirated. He had met with many cases of pleurisy with effusion and pneumonia following or accompanying "grippe," and sometimes it was difficult to make the diagnosis. He had seen cases in which there was no marked diminution of vocal resonance and no absolute dulness or flatness on percussion. He had been unable to explain this to himself, but thought it was due to the differences in the thickness of the chest wall and the different capacities of different chests. All of these reasons seemed to him at times to explain an error in diagnosis. Some men seemed to have a dread of aspiration for some reason—probably because they feared evacuation of the fluid in acute fibrinous pleurisy would increase the danger of adhesions forming, and also that the pleurisy might be changed into an empyema. He was also of the opinion that in a limited number of cases the application of a small blister to the area of pleuritic inflammation is almost always a means of aborting the inflammatory condition, and will sometimes prevent the formation of fluid in the chest.

He laid great stress upon the fact that the majority of these cases have no tuberculous taint. This was especially true of cases among the better class of patients. The sputa of such patients should always be examined for tubercle bacilli. The salicylates he considered of but little value in the treatment of pleurisy, unless manifestations of underlying conditions showed over and above the pleurisy.

Dr. Charles E. Quimby said that he regretted that he had not had the success promised by Dr. Delafield in treating pleurisy by aspiration, although he was willing to say that this might have been due to lack of care in other ways. According to statements made in the discussion in regard to the etiology of the disease, there are two classes of cases—those in which the disease is due to bacterial origin, and those in which it is dependent upon the development of a toxin, *i. e.*, ptomain poisoning. He did not believe that good results could be obtained by treating these two classes of cases in the same way, for one is due to the presence of a distinct bacterium and the other to the existence in the blood of a substance which is soluble and capable of being absorbed. He could not help feeling that lack of knowledge as to the etiology of the disease had very much to do with the difficulty in determining what line of treatment should be employed. These cases have very different constitutional symptoms, which are dependent not so much upon the resisting powers of the patient as upon the primary cause of the disease. He found himself treating pleurisy by means of calomel and Warburg's tincture, not thinking of the pleurisy itself, but of the toxemia which caused it. Of course, the administration of such drugs had no effect upon the first class of cases, *i. e.*, those due to bacteria.

He had been in the habit of using the pneumatic cabinet referred to by Dr. Page, and thought the benefit derived from it was due to the chest gymnastics, which causes expansion of the lungs and improves the local circulation, and not to any direct pulling upon adhesions. Hill climbing had a similar effect. He thought that any attempts at breaking up adhesions, if carried too far, would increase them, but that any exercise which will improve the pulmonary circulation will relieve the contraction of the lung, which is marked by shortness of breath that is so distressing, unless the lung has gone on to complete contraction. In one case of his, in which the diagnosis had been made by Dr. Janeway, the whole upper part of the lung was covered with adhesions, and there were abundant sticky, plastic râles, and the patient was becoming worn out and thin; relief followed the systematic use of the cabinet.

Nothing had been said about the cough of dry pleurisy. He was convinced that there is no such thing as a useless cough, and the cough of dry pleurisy showed that it is intended to irritate and stimulate the circulation, just as nitrate of silver stimulates the circulation of the tissue upon which it is applied.

Dr. W. H. Katzenbach was glad to hear mentioned the importance of cardiac displacement and mensuration in the diagnosis of pleurisy, and thought many doubtful cases might be cleared up by these means. Regarding the use of the salicylates, he had employed them with good results, especially in rheumatic patients. He was in favor of early aspiration in sero-fibrinous pleurisy, generally waiting until after the first stage, which lasts a week or ten days, but not always until the fever has subsided. The point he selects is at the angle of the scapula, usually in the eighth space, because there one can get near the point where the fluid gravitates. He had withdrawn as much as four or five pints without ill effects, and preferred to use an aspirating needle rather than a hypodermic needle, because of the larger diameter of the former.

Dr. Egbert Le Fevre said that when we remember the curved line of Ellis is formed by the rising of the lung, it is of great diagnostic significance in determining whether there is fluid present in the pleural cavity and whether there is a pathologic condition of the lung which prevents it from retracting and exercising a suction action upon the fluid and rising up in the axilla. In this way it is possible to determine whether the pleurisy is primary, or secondary to some other diseased condition of the lung. In regard to the absence of whisper resonance in empyema, he had seen cases in which it was distinctly marked. As to the treatment of pleurisy with salicylic acid, he referred to observations which had been made in which salicylic acid had been found in the pleura almost immediately after it had been administered, and that, therefore, it was probable that it had a local curative action.

Dr. Page, in closing the discussion, said that cases in which there was fluid at the top of the chest were very rare. He had only seen one case, and that had proved to be a hydatid cyst. Regarding aspiration of the pleural cavity in pleurisy with serous effusion, he did not think he would aspirate on the third day, in spite of what had been said. He would wait at least two weeks. He referred to two communications which he had received in connection with his paper, the substance of which was as follows :

Dr. Frederick C. Shattuck of Boston: My teaching from Bowditch and others was not to tap pleural effusions unless their size made them urgent in the acute stage. This practice I followed for awhile, but as time has gone on and personal experience has accumulated, I have been led to tap earlier than formerly, and, I think, with benefit. I tap now: (1) Large effusions, of course, immediately, not, however, attempting to empty the cavity. I stop as soon as constriction of the chest or cough or pain is at all marked. (2) A chronic effusion I also tap promptly unless it is a complication of *pulmonary* tuberculosis; in this case I may delay. (3) Acute pleurisies with effusion moderate in amount I do not tap, as a rule, unless they give rise to discomfort. I wait a week or so for spontaneous absorption, aided by dry diet and purgatives. But I do not wait for fever to subside to interfere, and have thought, in a number of cases, that the disappearance of the fever was hastened by operation. It would seem reasonable to think that if we wait too long tough adhesions are more likely to form, rendering the reëxpansion of the lung more difficult, and complete restoration more tardy. When I believe the fluid in the chest is under tenison, I do not use the aspirator, preferring the gentle and more uniform force of siphonage.

In most cases I do not believe it possible to entirely empty the chest with the needle or trocar. Oftentimes the removal of a moderate amount of the fluid seems sufficient to start up absorption of the rest.

Dr. James Tyson of Philadelphia: (1) By far the most reliable physical sign of pleurisy is absent or diminished fremitus, in my experience, almost witheut exception. I am aware, that, in the empyemas of children, it is said that fremitus is sometimes increased, but, though my experince is not large in that line, I have not met such a case. (2) I rarely find it necessary to use the needle in diagnosis; indeed, almost never. I see, however, very little or no danger in it, provided it is used with aseptic precautions. (3) I cannot say that I have been often able to verify the curved line of Ellis, but it may be that I have not been often forced to do so. (4) The treatment required varies so much with the severity of the disease that it is not easy to state it briefly. In severe cases, with extensive involvement of the pleura, wet cups are decidedly the most efficient remedy for the relief of pain and cutting short the process. Between hot and cold applications the former is the more satisfactory, but neither is sufficient to relieve pain when it is severe. Even large hypodermic injections of morphin are temporary in their effect, while wet cups are permanent and lasting. Strapping the chest with strips of adhesive plaster is a helpful measure.

In limited areas of inflammation, I use blisters and hypodermic injections of morphin for the relief of pain.

I have not used sodium salicylate largely, and prefer the iodid of potassium for promoting the absorption of effusion.

I do not aspirate early in the attack unless the patient is in danger from the excess of effusion, preferring to await the abatement of the fever, because while this lasts I consider the inflammation as still going on, and that the fluid will reaccumulate. Where the effusion is not large, I prefer to wait awhile to give Nature a chance to assert herself, aided, if possible, by the iodid of potassium, blisters, diuretics, purgatives and dry diet. Often these measures suffice. When I tap I generally take away all I can get, though I have not infrequently been compelled to desist because of pain and coughing. I always use the aspirator. Empyemas I hand over to the surgeon for drainage. Simple sero-fibrinous effusions, which are promptly followed by recovery, I do not consider of tubercular origin, though I believe empyemas are.

I have not heretofore availed myself of hill-climbing or the pneumatic cabinet in the after treatment, though I recommend patients to use gymnastics which favor the expansion of the chest and inflation of the lungs.

(5) One word with regard to sudden death in pleurisy with large effusions. It is an ever-present menace to me, because within a year past it has happened to me to have a patient in a condition of supposed convalescence, and to have him die within two hours after I left him. He was a clergyman between thirty-five and forty years old, who acquired a pleurisy in which the effusion took place rapidly, and the right pleural cavity soon filled up almost to the top, and aspiration became necessary. I never had a case of sudden death during tapping, but for some reason I feared it in this case. I tapped him while he was lying down, removing a large quantity of fluid, but not all. He seemed much relieved, and, as I have already stated, I considered him convalescent when he died suddenly. On autopsy I found a good deal of fluid still present, and I think it had reaccumulated after the tapping. No cause could be found for the sudden death. There was no valvular lesion, though the heart appeared softer than natural, but without microscopic examination.

REVIEWS.

MODERN GREEK MASTERY. A Short Road to Ancient Greek. By THOMAS L. STEDMAN, A.M., M.D. New York: Harper & Brothers. 1896.

The purpose of this new introduction to modern Greek is well explained in the preface. The author believes that the study of the modern language, as he represents it, is the best road for a student to take who is desirous of becoming acquainted with the literature of ancient Greece. He also cherishes the idea that the so-called "pure" modern Greek (*γλῶσσα αθαρεύουσα*) may become a common medium of expression for international congresses and the like. These views are not held by any large number of competent scholars, though it would be unfair to say that they have not been advocated by some whose opinion is entitled to respect.

A modern Greek learner has unquestionably considerable advantage over a foreigner in beginning study of the ancient language. Of course, his ear is already accustomed to the sound of many words in the ancient literature, and the new vocabulary will give him comparatively little trouble. For the more advanced student, however, the modern language is not especially helpful. Is it worth while then for a foreigner who wishes to learn ancient Greek, but who cannot have the training for his ear which a visit to Greece might give, and is thus debarred from putting himself in the place of a Modern Greek beginner, to take the time from his reading of the easier Attic authors and from his study of the excellent short grammars of the ancient language, which are at the disposal of every student, that he may master the highly artificial dialect which is set forth in such books as this of Dr. Stedman, and in others like it? Most people will say that it is not worth while. For this dialect is artificial. It is not the language *spoken* throughout the Levant, nor is it the language of the real literature of modern Greece—a literature which is redolent of the very soil from which it springs, and is the foundation upon which there is still hope that a more highly developed literature may some day arise.

To discuss such questions is not within the province of a brief notice like the present one. It is enough to say that Dr. Stedman's statement on pp. iv. and v. of his preface in regard to the relation of modern to ancient Greek and the analogous relation of modern to early English would not generally be admitted. And, if this is not admitted, his theory as to the best method of approaching the study of the ancient language cannot be accepted.

In regard to the possibility of using this "reformed" language in international deliberations—that is a matter for the future to decide. When one is able to hear it in a running *ex tempore* debate in the Athenian *Βουλή*, its adoption by foreigners may seem more likely than it at present does.

But, if we cannot take the point of view which the school represented by Dr. Stedman advocates, this point of view once taken, his book may be highly commended. If the student wishes to learn to read the more important Athenian newspapers or the New York *'Ατλαντίς*, the *Modern Greek Mastery* will be an excellent guide to him. On the other hand, if he wishes to travel in Greek lands and to know the cordial and interesting Greek of the village and country, he had better turn to other books for help. When his host gives him a morning greeting and asks the familiar question, *κοιμήθηκες καλά, κύριε;* he will have to turn to Dr. Stedman's *appendix* to know what the singular k-form can mean. Such forms are "vernacular;" in other words, they are what the modern Greek learns at his mother's knee, and what he commonly uses when speaking naturally.

The general plan of the book seems admirable, and the exercises are excellently adapted to their purpose. The typography, also, leaves nothing to be desired. The simple and clear statement on page 5 of the twofold pronunciation of x is a matter too often overlooked.

TRAITÉ DE MÉDECINE ET DE THÉRAPEUTIQUE. By P. BROUARDEL, A. GILBERT, and J. GIRODE, Assisted by a staff of collaborators. Paris: J. B. Bailliere et fils, 1895.

THIS stupendous work promises to be a system or cyclopedia of medicine, rather than an ordinary treatise. Brouardel is so well known that any work emanating from his pen is deserving of careful perusal and study. Among the collaborators are to be found names which have become famous in French medical thought and investigation. It would be invidious to single out such names as Deschamps, Dupré, Galliard, Gaucher, Graucher, Hallopean, Hanot, Hayem, Lancereaux, Landouzy, Laveran, Netter, Roger, Tessier, Widal, and Wurtz as deserving of special mention among the other equally famous men who have lent their aid to what promises to be (if we may judge from the first volume) a monumental work on French medicine.

The work will be published in ten volumes. Judging from the amount of space devoted to each subject in the first volume, ten volumes the size of the first, which contains 814 pages, will be insuflicient to complete it, or the subsequent volumes will have to be increased in bulk, or, finally, the matter in the other volumes will have to be condensed and contracted to keep the work within the proposed limits.

The first volume deals with the microbic diseases. The various chapters therein are very complete, and represent the knowledge thus far acquired concerning the diseases discussed. There can be no doubt that the subjects are extremely well treated, and among them may be mentioned that on scarlatina, by Wurtz; grippe, by Netter; diphtheria, by Graucher and Boulloche; an excellent article on streptococcic infection, by Widal; pneumonic infection, by Landouzy, and, finally, one on typhoid fever, by Brouardel and Thoinot. We notice with pleasure that in some of these articles race hatred is put aside, and that free credit is given to German thought and German methods of treatment.

ANNOUNCEMENT.

MINIMUM REQUIREMENTS OF THE PENNSYLVANIA STATE BOARD OF HEALTH, FOR THE PRODUCTION OF VACCINE VIRUS, ANTITOXIN, TUBERCULIN, AND OTHER ANIMAL PRODUCTS USED IN MEDICINE.

I. *Location of Establishments.*—The open country, or the suburbs of a town or city, should be selected. In such locations cattle will be more easily secured, the air will be more wholesome, and the disposal of manure can be more satisfactorily accomplished. Great care should be taken to secure a dry, warm, and sheltered location, with every facility for complete drainage.

II. *Buildings.*—The buildings should be erected with all known sanitary requirements in mind. They should be warm and sunny in winter, and cool and dry in summer. Complete arrangements should be made for ventilation and sewering. Windows should be numerous, for changing of the air when needed. Blinds and fly-screens should be provided for summer. Wooden stables should be preferred to those of stone or brick, because they can be kept dryer. Brick buildings, with air-chambers in the walls, however, will answer.

There should he at least two stables and an operating-room. One stable should be for the reception of cattle and for those which have been operated upon. Here the cattle may be tested and examined. The second should be the incubating stable. The operating-room should not communicate directly with the incubating stables, but by a passage. It should be well lighted by windows and sky-lights, and have abundant means of ventilation. The walls may be either of matched boards and painted, or of plaster, which should be frequently whitewashed. The floor may be of concrete, and so constructed with drains that they may be easily washed and kept absolutely clean. All the woodwork of the stables should be of smooth finish, to permit of ready cleansing and disinfection.

III. *Qualifications of Proprietor or Superintendent.*—The person in practical charge of vaccine production should be either a physician or a veterinarian, trained in general sanitation and hygiene, bacteriology and pathology. He should have an intimate knowledge of the pathology of infection, and of the principles of *asepsis* and *antisepsis*. He should be trained in animal pathology, especially on the subjects of septicemia, tuberculosis, Texas fever, anthrax, glanders, foot and mouth disease, and skin diseases.

IV. *Choice of Animals.*—1. The age of cattle should not be under three months nor over thirty months.

2. The history of the cattle should be minutely inquired into. Any with tubercular history should be excluded. All animals previous to admission to the stables with other animals should be carefully tested with tuberculin. They should be subjected to rigid physical examination. Any with persistent fever or cough should be at once excluded. Strong animals should be used, never those that are pregnant or those which have recently calved.

V. *Care of Animals.*—1. Animals should be treated kindly and considerately. They should be allowed to rest after arrival. They should be carefully cleaned, and clipped if needed; every day they should be carefully groomed and any sores or injuries attended to.

2. They should be well fed and watered. Good food should always be chosen. Any very dust-bearing food in a dry state should not be used. The food at some time in the day should contain grain. Hot mashes are useful. The water supply should be ample. Animals with fever, like human beings, need water. Hay and other food should always be absolutely free from mold. Bran and sweet corn chopped with hay are the best winter foods. In the summer time such crops as green rye, green wheat, grain, cow peas, German millet and

sowed corn may all be used. Ensilage should not be fed. When any animal refuses to eat or drink for twelve to twenty-four hours, the vesicle will abort and should not be used.

The stables should be kept *absolutely clean*. This is secured by having one man devote his whole time to this work, and droppings should be removed at once. The stables should be liberally bedded with clean wheat straw (oat straw should not be used), swamp hay, dry sawdust, or German peat. The latter, from its great absorbent power and antiseptic action, is highly commended.

In the winter term a temperature of 62° F. is correct.

Under no circumstances should the cattle be confined by immovable stanchions.

At least twice a year there should be a general and complete house-cleaning. The woodwork should all be scrubbed with hot water and soda, and then wiped with a solution of mercuric chlorid.

VI. *Precautions in Operating*.—1. The animals should be fed properly and washed thoroughly, if necessary, in such a manner as to render them practically antiseptic before operation.

2. The operating room shall be at all times aseptic; floors, walls and ceilings must be of matched hard pine, or other hard wood, and oiled. They shall also be washed in bichlorid of mercury solution from time to time.

3. The operators shall, before operating, render their hands and instruments aseptic, and put on a clean garment covering their other clothing, which garment must be washed and boiled as often as it becomes soiled; they shall also wear a cap of like material, and treat it in the same manner, or disinfect the head and hair thoroughly.

4. All operations, and the care of virus after taking, shall be under the supervision of a competent bacteriologist, and no virus shall be taken from any calf until it has passed his inspection.

5. Inoculations may be made on escutcheon, back, or belly. The first is preferred.

6. Instruments, hands of operator, skin of animals, and all apparatus, should be kept sterile at all times. Points, tubes, or other containers should be sterilized by heat.

7. The seed should be good, clean lymph. Lymph tinged with blood may be used; it is often the best. Crusts or pussy lymph should not be allowed as seed.

8. Antiseptics should be freely used on the skin after shaving and before inoculation.

VII. *Collecting the Lymph*.—The lymph is collected from the fifth to the seventh day, as determined by the areola and the temperature of the animal, which now reaches the highest point, *viz.*, 102–104° F. The virus is always taken before the vesicle reaches the pustular stage. The vesicle is well sponged with warm water, the crust removed, and the exuding virus collected on a sterilized camel's hair brush and transferred to sterilized ivory points, or collected in sterilized vials or glass tubes. The old method of dipping the ivory points into the vesicle, being painful to the animal and non-hygienic, should be discontinued. No pressure should be used on the vesicle, which should be allowed to yield its lymph of its own accord.

After the lymph has been secured the vesicle should be well oiled, and the animal carefully protected for several days, after which it may be removed to the first stable until convalescence is fully established.

VIII. *Care of the Lymph*.—The virus may be placed on the market on ivory points or quills, or in tubes and vials.

Points and quills should be carefully dried in a sterilized receptacle and put up in sterilized paper, or sterilized metallic tubes or bottles, and sealed. Virus to be placed in vials or tubes is first mixed with chemically pure glycerin, and then sealed hermetically. As an additional preservative trikresol may be added.

Every package of virus must have on it the name and address of the propagator, and the date when the virus was taken.

No vaccine virus will be approved by the State Board of Health of Pennsylvania unless propagated in accordance with the provisions of the aforesaid rules.

IX. *Requirements for Diphtheria Antitoxin, Tuberculin, Mallein, and Other Animal Products Used in Medicine*.—The establishments for the production of these animal products shall possess all the sanitary requirements as for vaccine production. They shall be in charge of a person trained in medicine, bacteriology, general sanitation, and pathology. The animals employed shall in all cases be strictly healthy, and shall be cared for in a healthy and humane manner. The premises shall at all times be kept *absolutely clean*. All operations shall be performed with the greatest possible care, observing all known antiseptic precautions.

X. To receive the certificate of the Pennsylvania State Board of Health any establishment producing any animal product used in medicine must at all times be freely open to the Board, its agents, and inspectors. Every such establishment must be conducted in such manner as the Board directs, and must submit to inspection by experts in bacteriology, pathology, and veterinary medicine so often as the Board may direct. All the processes employed, both in the production of the products, as well as in their preservation, must be made known to the Board.

XI. No preparation of antitoxin, tuberculin, mallein, or other animal product used in medicine shall be offered or exposed for sale in Pennsylvania unless the receptacle containing such preparation bear a label, or upon a circular accompanying such receptacle and enclosed with it in a sealed package, shall be printed or written the date of the production, and the value of the contents in antitoxin (or other products) as measured by some generally recognized standard.

XII. All certificates issued by this Board for animal products shall be dated, and shall be good for one year only, which shall be stated in each certificate. They may be revoked for cause at any time.

G. G. Groff,
Chairman Committee on Preventable Diseases.

VOL. LXX. NEW YORK, SATURDAY, FEBRUARY 20, 1897. NO. 8.

ORIGINAL ARTICLES.

THE DIAGNOSIS AND TREATMENT OF POTT'S DISEASE OF THE SPINE IN THE ADULT.[1]

BY V. P. GIBNEY, M.D.,
OF NEW YORK;
PROFESSOR OF ORTHOPEDIC SURGERY IN THE COLLEGE OF PHYSICIANS AND SURGEONS; VISITING SURGEON TO THE HOSPITAL FOR RUPTURED AND CRIPPLED.

IT has often been stated in public discussions that Pott's disease of the spine as it occurs in the adult is a most inveterate and intractable disease to treat, and that the patient submits very unwillingly to any form of restriction. It has been further stated that apparatus is not so available as it is in the disease occurring in childhood, and that when an abscess appears the prognosis is necessarily grave. Very few of the text-books dwell at length on this subject, and for this reason I have made an effort to collect a few typical cases that will illustrate the ease with which the disease can be managed by adherence to principles which govern us in the management of the affection in childhood and adolescent life.

Before proceeding to the narration of cases, I should like to present some points for discussion in the diagnosis of Pott's disease, and to illustrate these features by clinical records. In selecting material for illustration, I find complete notes of a number of lesions or diseases that simulate Pott's disease, such as irritable spine, with neuroses of hip or knee, railroad spine, hysterical spine, multiple osteo-myeletis, in which the spinal column participates in the disease, fracture of the spinal column, rheumatic spondylitis, and malignant disease of the spine.

1. NEUROSES OF THE SPINE.

In a fair proportion of the adult patients referred to me for an opinion, or seen with the family physician for some obscure spinal lesion, I find an irritable spine. The pain in the back has usually been an annoying feature, a faulty attitude in standing or walking, the tenderness on concussion, have all conspired to bring about a degree of anxiety, which has for some time distressed the patient, and which finally demands of the attending physician an examination of the spinal column, and occasionally ends in a diagnosis of lateral curvature. Running the finger over the spinous processes, then over the lateral masses, he detects points of tenderness which are at least suggestive, and he naturally finds a tuberculous disease of the bodies of the vertebræ, or, what he more frequently feels called upon to name it, a traumatic Pott's disease of the spine, because of a history of injury. If he were familiar with the more recent literature of Pott's disease of the spine he would attach a different significance to the tenderness. He would naturally exclude disease of the body of the vertebra, because he would be unable to trace any connection between the suspected body and the skin so far removed, or processes spinous or transverse. The family physician is more easily annoyed, however, by the history of a fall or a strain of some kind, and not having acknowledged his firm belief in all the teachings that have grown out of the discovery of Koch, he is loath to accept any other theory than the traumatic. I offer the foregoing explanation as one reason why it is so difficult to make a diagnosis. The chief reason, however, is the lack of confidence in one's opinion, the lack of courage in one's convictions and the failure to make a thorough examination.

Again, the prominence given to the reflex nature of many of these diseases has tended to impair the observer's confidence in his own findings, and he looks for some cause in the muscles of the eye, in the functions of the ovaries, or in the condition of the genitals.

CASE I.—Traumatic neuroses of the spine. Miss T., aged twenty-two, from one of the Northern towns in this state, was referred to me by Dr. W. T. Bull, April 29, 1895. I obtained the following history: Eight years prior to this date the patient fell from a second story window in a fit of somnambulism, and on being lifted from the ground, complained of her wrist. With the exception of a little general soreness she complained of nothing else. Nearly six months later she had pain in the back, and during the following year had peculiar sensations like that of snakes crawling along her body. For the relief of this she would resort to various kinds of plasters. Three years later, in the spring, she had an attack of neuralgia, which her local physician regarded as an attack of the grip. On recovering from this she found that the back was much more painful. It was fully three years after the initial neuralgia and two years prior to the date of my first observation, that her distress was so great as to require for its relief a plaster of Paris jacket. Her report was that this did give relief, and that she was comfortable as long as she wore the jacket. On one or two occasions it was removed by way of test, but her pains became intolerable.

---

[1] Read by title at the ninety-first annual meeting of the Medical Society of the State of New York, Albany, January 27, 1897.

Although the menses were not normal she was regarded by the family physician as free from any disease of the uterus or ovaries. She had complained of pains around the knee, not directly in the joint, and also in the thigh and calf muscles. She walked with a decided limp. In my examination I found the left knee from a quarter to a half inch smaller than its fellow, and much tenderness of the skin and the tissues lying directly thereunder. The thigh and calf presented the same tenderness. There was no fluid in the joint; she could extend perfectly, and could flex beyond 90° without pain or discomfort. The spinous and transverse processes in the dorso-lumbar regions were especially sensitive. I was compelled to make my examination while she was partially suspended in the swing, because she dreaded to stand even without the jacket, assuring me that if this were done she suffered pain in the back for hours. I found a little fulness in the dorso-lumbar region, or rather an obliteration of the normal curve. The column I could move quite freely, if carefully done. The tenderness was quite marked in the distribution of the nerves, as well as in the ovarian region. I had no difficulty in making a diagnosis of a neurosis of the spine with involvement of the knee, and proceeded to treat her accordingly. I made a light steel brace which could be removed several times during the day, and resorted to the cautery for the relief of pain. Within a fortnight she was very much relieved, and could go without her brace for a part of the day. About this time she returned to her home, and when I saw her again, December 19, 1895, there was little or no tenderness on concussion, none on lateral motion, but rather sharp tenderness in the lower dorsal region. She reported to me another injury of recent date, but her brace protected her and she came off with very little harm. In a letter under date of May 20, 1896, I learned that she had discarded the brace, had been wearing an ordinary corset for the past two months, had very little backache, and was delighted with the result of treatment. This case was used to illustrate the apparatus in a paper on the "Management of Irritable Spine," read before the Practitioners' Society, April 3, 1896, and published in the *Medical Record*, May 9th. In further illustration of this part of my paper, I would refer my readers to the communication to the Practitioners' Society.

While I am not able to give all the points in differentiation between an irritable and a hysterical spine, I may present an example of what I take to be hysterical spine.

CASE II.—In September, 1884, a gentleman, aged twenty-seven, applied to me for a plaster of Paris corset, stating that he had worn these jackets since 1877. I found him a robust hearty-looking individual, without any marked bony deformity. Indeed, I had some difficulty in making out any deformity. There was a certain amount of rigidity in the dorso-lumbar region, but he declared that it was simply impossible for him to get on without support. When twenty years of age, seven years prior to the date of my first note, he suffered from pains in the lower limbs and a slight spinal stiffness. He knew of no cause and did not attribute his disability to any injury. Under the advice of a distinguished surgeon in this city he got a plaster of Paris jacket, and had continued that treatment. I suggested to him a leather corset, which would amount to nothing more than a broad leathern belt about his loins, and made one for him. Six or seven years later I examined him again, with negative results. He was still wearing the leather jacket, and had, at times, worn one made of canvas. It was a matter of surprise to me that he persisted in this support, or regarded himself as at all unwell. All of his organs were pretty thoroughly examined, with absolutely negative results. This was June 5, 1891, and in May 17, 1892, he developed certain neuroses involving the genitals; indeed, I found a slight hernia on the right side and applied a truss. He was so much disturbed mentally that I referred him to my friend, Dr. Sachs, who wrote me that this was a case of somewhat aggravated sexual neurasthenia, with weakness of the genital organs. Suffice it to say that he got relief, and as late as December 12, 1895, I made him two or three canvas belts, which he uses to this day.

The difficulty of making a pathological diagnosis in a case of this kind is not to be under-estimated. If this were a case involving a suit for damages, one would naturally say that it was purely hysterical, and that the patient would get well just as soon as a verdict was rendered, but this gentleman has never been able to assign any cause to his trouble; has never nursed any suit for damages.

We are so prone to attribute most of the cases of railroad spine to hysteria, that I shall present one or two by way of illustration.

CASE III.—On March 10, 1891, Dr. J. A. McCreery of this city referred to me a man, aged thirty-two, who was severely injured in a tunnel accident two and a half weeks prior to that date. In the accident he fell backward, striking on an iron casting. He was able to walk about for three or four hours after the accident before being compelled to seek rest. From that time he complained of more or less pain, and was unable to walk without considerable effort.

I found him well developed but quite distorted in body. There was an irregularity of the spinous processes of the last dorsal, and the first, second, and third lumbar vertebræ. In this region he was exquisitely sensitive. The erector spinæ muscles on the left side were more prominent than those on the right. He stooped forward and the natural position was a slightly bent one, and when he attempted to stand more erect this little irregularity of the spinous processes still existed. There was pain on concussion and a slight antero-posterior curve in the region just mentioned. He was also sensitive in the iliocostal space, and attempts to turn himself from side to side caused pain, so he stated, and so he manifested by his expression. There was nothing in the iliac fossa, except apparent tenderness and this was superficial. Hyperextension of the thigh was made easily on both sides, but there was more psoas resistance on the right. There was no impairment of functions at the hips or the knees, but tenderness in the left iliocostal space, as compared with the right. I recognized also resistance in this region to the pressure of the fingers, and could easily map out what seemed to be a distinct tumor. I was, however, unable to satisfy myself of the existence of any bone lesion, and advised the cautery quite freely in the sensitive region. Six days later he reported and I could note about twenty-five per cent. improvement, and advised him to resume work. Dr. McCreery had found him, a day or two after the accident, doubled over very much, and quite unable to work, so he applied a plaster of Paris jacket, which afforded some relief, and at the doctor's suggestion, I renewed it on the 20th of May. Two days later the patent reported himself as greatly improved; could walk more nearly erect, and did not have so much pain or distress in the posterior parts of the thighs. He had already begun a suit for damages, and as requested, I gave a certificate on the 25th of June to his attorney, to this effect: I had regarded his case as one of contusion of the back and loin, but he had not responded as promptly to measures of relief as I had hoped he would, and I now found him suffering from symptoms that pointed toward Pott's disease of the spine, although I was unable to demonstrate the conditions. I gave it as my opinion that he would require protection treatment for at least eigh een months or two years, and that I was unable to state positively what the outcome would be. The treatment adopted was very thorough and I kept him well supported in jackets, employing the cautery two or three times a week, and yet, by the 8th of September, 1891, I was unable to confirm the diagnosis and to give a favorable prognosis. It is only fair to state that a settlement of the suit had not been reached. On the 15th of September, 1891, I reported his case in a paper: "The Early Diagnosis, the Best Treatment in Pott's Disease of the Spine," read before the Canadian Medical Association in Montreal.

From July 5, 1895, I saw him occasionally, more frequently during the years 1891 and 1892. I employed by way of treatment, the corsets, cautery, and potassium iodid. In March, 1892, he had some peculiar neuroses, such as twitching of the face, pains in the lower limbs, cold feet, cold ankles, etc. About this time he effected a settlement with the company and went into business. A few months after this it was reported to me that he was doing well, that he was working pretty much all day, and that he was able to get on without the support of the plaster jacket, but with a corset heavily reinforced with steel. When I examined him last, July 5, 1895, his spinal column was still irritable and sensitive. He had no longer any reason to expect any relief from the company. Indeed, he was not embarrassed by a lawsuit. During the past year I have seen him but have not made an examination. He is still wearing some sort of a support, but is attending to his business and will probably make a good recovery.

2. RHEUMATIC SPONDYLITIS.

In employing the term spondylitis, I wish it understood that the lesion is a periosteal thickening along the lateral masses and involving the foramina of exit for the spinal nerves. It may involve more than the foramina by extension, and produce ankylosis, more or less complete, of the column. The periostitis is usually rheumatic. The term "spondylitis" was used a great many years ago by Dr. Julius Braun, who lived at one of the bath establishments in Europe, and who wrote a very elaborate article on this subject. The cases he reported had been regarded as cases of irritable spine, but by adopting antirheumatic treatment, coupled with vigorous hydrotherapy, he was enabled to effect a cure in a large percentage of his patients. The process, therefore, is not a tuberculous one, and does not involve the bodies of the vertebra.

Case IV.—A gentleman, fifty-two years of age, was referred to me by the late Dr. Alfred L. Loomis on November 15, 1890. His symptoms dated from October, 1889, about which time he had a severe cold, and was very active in business. Two months later he was severely chilled while traveling in a cold car, and suffered at once from rheumatic pains. Indeed, he was confined to his room for a period of two weeks. A month later he had an attack of the grip, and was treated for rheumatism. During the following spring he sought relief at Clifton Springs, then at Fortress Monroe, and later at Nantucket. During the summer he got some relief, but, returning to his home, was in a wreck on the railroad, and was considerably bruised. It was fully two months after this that he had a return of his old symptoms. He complained, in addition to this, of a girdle pain just below the mammary line. Dr. Loomis himself looked upon the case as one of rheumatism, but for the spinal symptoms referred him to me for treatment. When I examined him he was in fair health, but walked with his head bent forward, and very carefully. He took short steps, and seemed to be continually guarding against concussion or jar. There was a prominence of the spinous processes of the eighth and ninth dorsal; there was tenderness on pressure and on concussion. There was a point of tenderness over the vertebra prominens, but he was able to move his head very freely, and pressure against the anterior portions of the vertebræ, through the pharynx, did not give rise to any pain. I was a little uncertain myself as to the nature of the disease for which he sought relief, but there were enough symptoms and signs present to warrant me in providing a fixation apparatus, and in employing the cautery. A few days later I found an area of soreness and tenderness along the outer side of the leg, just below the head of the fibula. On December 12th I saw the patient in consultation with Dr. Loomis, and both he and I questioned the existence of Pott's disease. The deformity, at this time, was not so marked. We agreed upon the potassium iodid and cod-liver oil. The brace afforded him some relief.

I heard from him by letter the latter part of January, 1891, and the report was excellent. On the 4th of March he was much improved, but he still complained of pain about his left limb and foot. The fulness in the spinal region, which had been noted at the time of my first observation had entirely disappeared, but the tenderness persisted. The cautery was employed, and instructions were given to have it continued at his home. I saw very little of him during the year 1891, but on several occasions I found a decided improvement. He was unable to dispense with the brace, but in 1892 was about as well as ever. He called upon me October 6, 1893, to report himself as perfectly well, and able to travel very long distances. I have heard from him from time to time, up to the present, and he still continues well, so I feel positive about the diagnosis.

Case V.—A gentleman, thirty-seven years of age, was referred to me by Dr. W. M. Polk, during the close of the past year. Two years prior to this he began to have some trouble with his back. His urine was acid and contained uric acid in large quantities. A year after the beginning of these symptoms he was rather stiff in the back, and walked like an old man. He was at this time examined by a distinguished orthopedic surgeon of this city, and on the strength of the rigidity of the column, and marked deformity, the diagnosis of Pott's disease was made, so the patient reports. A grave prognosis was given at the time, but treatment was not accepted. Instead of using the apparatus, he went to Carlsbad, where he obtained much relief. During the past year he has improved much, has very little deformity, holds himself much straighter, and attributes much of his relief to a course of massage. I found a slight anteroposterior curve from the middorsal to the third lumbar vertebra, but it was not angular. There was no tenderness on concussion; no pains in the course of the limbs. There was no reflex spasm in the psoas or iliacus when hyperextension of the thighs was made. I was unable to make a diagnosis of Pott's disease, but rather of rheumatic spondylitis, and later reports seemed to confirm it.

In arriving at my diagnosis I, of course, had the benefit of his history, and of his amelioration, without orthopedic treatment. Some cases present such marked evidences of rheumatism about other joints that one can very easily make a diagnosis where the spinal column is involved.

3. FRACTURE OF THE SPINE.

I think one is seldom at a loss to make a diagnosis in a case where a fracture has occurred, because of the history of great violence, even where the resulting deformity presents a bosse characteristic of Pott's disease. For example, take the following:

Case VI.—A stout, robust-looking man, thirty-five years of age, presented himself at my clinic, at the College of Physicians and Surgeons, on the 27th of April, 1896. The history he gave was that up to the latter part of 1891 he was perfectly well and quite active. In trying to couple some cars he was caught between them and suffered a slight injury, but there was no signs pointing to injury to his back and a month later he was at work again as night watchman. He continued well until the 19th of September, 1894, when he was thrown from a carriage and fell on his back. The fall dazed him for about five hours, during which time he was practically dead. He was removed to the hospital, but there seems to have been no diagnosis made. The patient himself states that his back was not examined, but he remembers distinctly that as soon as he recovered consciousness his limbs were absolutely palsied as to motion and sensation. The line of anesthesia was just below the umbilicus. There was retention of urine, and the bowels were moved by enema. It was fully three months before he was able to tell when he had a movement, except by the odor. Bed sores formed during his treatment, which extended over a period of six months. The reflexes became exaggerated during convalescence, and about seven months from the time of injury he was able to stand. Three months after the injury, however, he began to have control of his bladder and rectum. It was fully a year before he was able to walk about, and then the limbs presented a good deal of tremor, with reflex spasm, which was chiefly confined to the left lower extremity. He never wore any apparatus and never had any treatment directed to his back.

At the time of my examination there was a bosse extending from the tenth dorsal to the sacrum. The outline of this bosse corresponded exactly with that of deformity after Pott's disease. There was no spinal tenderness, he was free from pain, and there was no tenderness on concussion. The left foot was held in marked equinus, toes in hyperextension, and when he bore his weight on this limb it rested on the distal ends of the metatarsal bones. He could freely flex and extend the right thigh and right leg, but was unable to flex the left thigh unless he grasped the posterior part of it with the hand, and proceeded to "unlock" himself. After this maneuvre he could flex his thigh up to 90°, and could extend, but in the act of extension the muscles were thrown into a state of tonic spasm. From a number of other similar symptoms it was concluded that there was some pressure on the nerves supplying the left lower extremity, and that he had a spastic monoplegia due to compression.

The course pursued by the paraplegia in the case just reported, does not differ from that in the majority of cases, although the prognosis must depend upon the extent of the cord lesion. It is a good plan, in my judgment, to attempt reduction of the deformity at once under an anesthetic, if need be, so that the pressure symptoms may be avoided or promptly relieved. I do not enter into the question of operation, although I firmly believe that an operation done very soon after the injury is productive of enormous good to the patient.

4. MULTIPLE OSTEOMYELITIS, INVOLVING SOME PORTION OF THE VERTEBRÆ.

One occasionally meets with cases of multiple ostitis where the shaft of the long bones is involved, and where one seldom finds any involvement of the vertebræ. The inflammatory process may take in one or more ribs near the vertebral articulation, and when this does occur it is quite rational to suppose that the vertebræ themselves will be involved. The following case is illustrative:

Case VII.—A medical gentleman, aged forty, was referred to me by the late Dr. Loomis, on the 24th of November, 1894, and I made a diagnosis of non-deforming Pott's disease in the dorso-lumbar region. This diagnosis was based on the fact that he had suffered two or three years with pains and aches, referable to the spine and the nerves, but I did not take into account a possible neurasthenia. He had a stiff spine, which was tender, and the pains were referred to the course of the nerves. It was exceedingly painful for him to turn over in bed or to get up and down, although there was no pain on concussion. The movements of the column from side to side or forward and backward gave him pain. I advised a plaster of Paris corset, supplemented by the use of the cautery. He did not come under treatment at this time.

It was reported to me on July 10, 1895, that an abscess had appeared over the head of the tibia, right side, and that an operation had been done in March for the relief of this abscess. The sinus was thoroughly curetted, but was not relieved. Indeed, two sinuses existed at this time. There was already an abscess in the posterior femoral region and also in the left lumbar region. I had an opportunity of examining him on the 17th of July, at his home in New Jersey, when I found his right leg flexed at an angle of 90°. There was a large ulcer on the outer side of the fibula, with the bone almost in sight. It could easily be recognized by means of the probe. Indeed, the probe passed the denuded bone of the fibula and enabled us to discover denuded bone in the head of the tibia. The knee-joint itself seemed to be normal so far as appearance went, but there was an abscess above the knee, along the outer and posterior aspect, already discharging. Just below the anterior superior spinous process, and on the outer side of the ilium, there was a small tumor, which had lasted, they reported, for some weeks. The hip-joints seemed normal. Over the sixth or seventh rib, right side, about the middle, was a sinus which led to denuded bone. In the left iliocostal space, and a little to the posterior border of it, there was a good-sized fluctuating tumor. The spinal column still presented no deformity, but it was quite stiff. I learned at this visit that he had worn a spinal brace, applied by an orthopedic surgeon, for a period of two months, but on advice of his family physician it had been discarded.

On August 2d, assisted by Dr. Bull, and his physician, Dr. Terriberry of Paterson, I exposed the head of the fibula, right side, and removed it by means of a chisel. A focus of disease was found in the head of the tibia, and this was thoroughly curetted until hard bone was reached. This focus did not encroach upon the articular cartilage; indeed, there was healthy bone between the focus and the cartilage. Sinuses and abscesses in this locality were pretty thoroughly curetted and scraped, while the abscess above the knee was treated in the same way. The sinus over the rib was enlarged, when it was found that fracture had taken place at some time, but that union had not followed. The rib was resected for about one inch. The lumbar abscess was aspirated and about 4 ounces of pus evacuated. Further operative procedure was withheld for the time being. The patient rallied very well, and about two months later returned to his home.

October 3d, a second operation was performed, with the same gentlemen present, and on this occasion I made an incision over the lumbar abscess, just over the iliocostal space, extending it down into the sac, which contained a moderate amount of seropurulent matter. The track of this abscess extended upward toward the lateral masses of the vertebræ, to a point complained of as the location of a slipping sensation. The latter was well explained by extending the incision upward several inches, across the spinal column, where I finally reached necrotic bone about the articulation with the spinal column of the eighth and ninth ribs, where the ninth rib was found extensively eroded. After removing the periosteum which remained on the anterior aspect, I cut away the rib, leaving only about one-third of the entire bone. When the portion resected was removed, a purulent sac was found in front of the rib, and this was thoroughly cleansed. The articular facets and transverse processes were eroded and crumbled easily, so that by curettage, drainage was found to be pretty thorough. The incision was carried up still further, and the eighth rib, at the articulation, was treated in the same way. The neurosis involved the posterior segments of the vertebræ, especially those on the left side. The dura was not opened. It was noted on the 15th of October that he had had no temperature whatever since the operation, that his wounds were healing, and that he was moving his knee much better. During the latter part of the year, and indeed throughout the greater part of 1896, the patient made slow but steady progress.

Last summer the abscesses about the knee were so extensive that the limb was amputated about the middle of the thigh. The wound healed within a short time and he seemed to improve. In December, however, he presented signs of pulmonary tuberculosis, and shortly before Christmas he expectorated a large quantity of pus, which gave him great relief. The pulmonary signs proved to be those of an abscess, extending from his spinal column into his lung, through which it broke quite recently. It is reported that he is doing very well, is sitting up, but that two or three sinuses over the spinal column are still discharging. This case was indeed a very instructive one, apart from the keen interest felt in the case by his professional brethren.

The osteitic process, of course, has been proved to be tuberculous in nature, but it is curious to note that the compact structure of the bones was involved rather than the cancellous portion. Those of us who made a diagnosis of Pott's disease of the spine were in error, as the process did not involve the bodies of the vertebræ. It is perhaps to be regretted that radical measures were not undertaken sooner, but with the multiple lesions, it is quite difficult to see now how all of these foci could have been thoroughly removed. The two operations which Dr. Bull and I performed were certainly radical, but we were obliged to leave one or two abscesses, which have since disappeared. The presumption therefore is that the bacilli were induced to colonize in other parts of the body, and that our efforts have been of little avail.

5. MALIGNANT DISEASES OF THE VERTEBRÆ.

In approaching this subject I feel that it is difficult to lay down any hard and fast rules by which one may recognize malignant disease in its early stages. It is true that the disease, as a rule, attacks most frequently the female sex, and that the pre-existence or co-existence of a mammary tumor is sufficient to put us on our guard. Sometimes, however, the existence of this tumor is overlooked. The persistence of the pains in the course of the nerves which pass through the region involved, ought to, at least, suggest malignant disease, even when there is no mammary tumor to guide us. There are so many cases, however, where the tumor has been removed, and where a long period has elapsed between the removal of the tumor and the appearance of the first spinal symptoms, that one hesitates to make a diagnosis of cancer of the vertebræ until an opportunity has been afforded for several examinations. A few cases may serve as illustration.

Case VIII.—A lady, aged forty-five, came under my care on the 21st of July, 1893. I found her in bed with a pretty sharp deformity in the dorsal region. There was paraplegia of recent origin, and I made a diagnosis of Pott's disease. She told me that two years prior to the date of my examination, she had a sudden jar by falling down one flight of stairs. For two or three days after this there was a little stiffness, which finally passed off. It was a year later that she began to complain of pain in the right side, in the neighborhood of the free ribs, but the pains did not extend down the thigh. She did not think enough of these pains to consult a physician, but continued with her household duties until she found it rather difficult to get about. She was not able to clear the floor well with her feet. It was only recently that she had seen a physician, but her back was not examined and her pains were regarded as rheumatic in nature. She was in bed for a period of sixteen weeks, under treatment for rheumatism. She got up and tried to walk but the pains were so great that she took to her bed again, and five days before I was called she had lost the use of the lower limbs. It was exceedingly difficult to make a satisfactory examination by reason of the great suffering induced by attempts to move from side to side in bed. The lower limbs, as before stated, were completely paralyzed. She had incontinence of urine and of feces, to a moderate extent. There was a bosse in the mid-dorsal region, about an inch in height. Her abdomen was large and somewhat distended.

Admission to the hospital was soon secured, and with considerable difficulty, a few days later, I succeeded in applying a plaster of Paris jacket. While in suspension the deformity receded to a marked degree. That afternoon she began to move her toes and the relief to the paralysis was most pronounced. On the following day she was able to extend both feet and toes, and was very comfortable in the jacket. The urine, however, was retained, and had to be drawn by catheter, the pains persisted and I still did not give to the symptoms the proper interpretation. On the 4th of August, 1893, I made a plaster of Paris corset, and after the suspension the urine was voided naturally. The specific gravity was low, there was no albumin, no sugar. At this time she was taking pretty large doses of the potassium iodid and the cautery was employed every other day. The hospital treatment was continued throughout the summer during my absence, and the limbs improved very markedly, but the patient was still fretful and irritable at the close of the season and complained of great pain. I then began to surmise that she suffered from malignant disease of the spine, although there had been no breast tumor of any kind, nor had she been subjected to any operation. She was discharged in November, 1893, and gradually failed, dying on the 5th of December.

It is interesting to note that in the latter part of November she had a most unquenchable thirst, drinking large quantities of water, and still not satisfying her thirst. She had polyuria and her pains were so great that large doses of morphin were required for her relief. Autopsy was not secured.

Case IX.—An unmarried lady, aged thirty-two, from Denver, consulted me July 26, 1894. She had been referred for Pott's disease of the spine, and the symptoms had extended over a period of twelve months. She had travelled a good deal in search of relief. At the time I saw her I was able to make a very careful examination, learning that six months prior to this date a nodule was removed from the right breast, which operation included the axillary glands. The report brought me was that microscopic examination showed the tumor to be benign, but I questioned very much the truth of this, inasmuch as the pains she complained of were so excruciating. I was willing, however, to treat her symptoms, and did my best to give her relief by means of a jacket, cautery, and the milder narcotics. The case, however, progressed from bad to worse, and on the 6th of December I referred her to Dr. Wm. B. Coley for treatment by erysipelas toxins. Two or three weeks later the doctor reported that he had succeeded in alleviating the pain, but that the disease seemed to be advancing and that the case was practically hopeless. She died some weeks later and the case has already been reported by Dr. Coley.

I had no difficulty in making a diagnosis in the last case, but the following taxed my diagnostic powers to the utmost, and I am free to admit that I made an error. Just why I should have done so I am at a loss now to understand, because the signs were unmistakable.

Case X.—A lady, aged thirty-two, was placed under my care on the 13th day of October, 1895. The history she gave was the following: Four years before, at the time of her marriage, she was hearty, well-nourished, and in excellent health. About a year before her marriage she had the grip, followed by pneumonia, from which she made a slow but satisfactory recovery. Twenty days after her marriage she had a return of the grip, which was very severe, lasting two weeks. Five months later she had an attack of what was called appendicitis. This was in the summer of 1892. During that fall and winter she was comparatively well. In the spring of 1893 she began to have trouble with her nose and antrum. A number of polypoid growths were removed. She suffered much from what was called asthma or bronchitis during the spring and summer, extending even into the winter. In the spring of 1894 she was much improved. In the fall of 1894 her attacks of asthma recurred. Up to this time she had had no pain in the back. Her menstrual functions had been regular all the while, but she suffered much from constipation. Her asthmatic attacks proceeded during the winter of 1894 and 1895.

On the 15th of March, 1895, she had pain in the abdomen, girdle-like in character. Following this came long periods when she was much nauseated; sometimes for three or four weeks off and on. During these periods her bowels were obstinately constipated and she suffered from intercostal neuralgia. In the latter part of April a large mass of feces was removed by mechanical means. In May an attempt was made to walk, but she was quite stiff, and would complain bitterly of pain in the back, which pain was also referred to the hips. In June she had much difficulty in climbing stairs. The plaster of Paris jacket was used during the summer, but the suffering was unrelieved. She became more and more emaciated and at the time of my examination her condition was truly pitiable.

She was quite hysterical, and it was difficult to secure an examination by reason of the great tenderness on any movement, active or passive. The spinous processes of the upper dorsal vertebræ were unusually prominent, and there was a general anterior curvature of the spine in the dorso-lumbar region, but no distinct knuckle. The limbs were much emaciated but retained their power. I suspected Pott's disease of the spine, and although I found the ilium and ribs rather irregular and tender on pressure, I attributed these conditions to extreme emaciation. My diagnosis was extreme neurasthenia, with aggravated irritable spine. It occurred to me that a trained nurse was what she needed more than anything else, so I provided one, and suggested that a local physician be called. She remained under my observation until the 1st of December, when I met Dr. Van Santvoord, to whom I had referred the case. The doctor had previously written me after his first visit, which was on the 19th of November, as follows:

"I suppose that a tumor of the breast, lasting eighteen months, softened nodular ribs, and thickened pelvic bones, are not likely to result from anything but malignant disease, probably carcinoma."

When we met at the bedside I recalled the points which Dr. Van Santvoord had mentioned in his letter, with the exception of the breast tumor. I had not examined the breasts, nor had the patient or her husband at any time ever suggested to me that there was anything wrong about these organs. I learned on this date that this tumor had been under observation for a long while, and that its removal had been advised. I had nothing to do but admit my error. The patient died on the 12th of December.

Case XI.—With this case fresh in my mind I was called to see a patient, a lady, aged twenty-eight, on the 25th of August, 1896, in order that I might give treatment to a deformed spine. There was a well marked bosse in the dorsal region, and a history that the mother of the patient had, for several years, an epithelioma of the nose, that the grandfather had died of some "cancerous affection." The patient herself had had a weak back from girlhood, and had complained more or less from time to time. She was married at fifteen years of age, never bore children, and two years prior to the date of my seeing her she was curetted for some uterine disorder. At the same time the os uteri was dilated. She told me that at this time a small nodule appeared in the right breast, which had gradually increased, and which had been pronounced by her physicians to be carcinoma. In February, 1895, the back began to be painful. She remained in bed from March until July, under treatment for rheumatism. She sailed for Europe in July, but placed herself under treatment in Boulogne, France, shortly after her arrival. The spinal deformity was recognized and a plaster of Paris jacket was applied, which jacket gave her relief. When I made my examination there was a tumor in the right breast, involving pretty much the whole of the organ. It was nodular and hard while the nipple was retracted. The axillary glands were not enlarged. She had a marked kyphosis extending from the mid-dorsal to the lumbar vertebræ. This deformity had been present for about six months. Dr. George T. Harrison saw the case in consultation with me and agreed as to the nature of the trouble. I made a diagnosis of malignant disease of the vertebræ, probably carcinoma. She was fitted with a corset jacket, and went into the country, returning about the 23d of December, and when I saw her on the 25th there was a rapidly increasing paralysis of the lower extremities, attended with retention of urine. On the 19th, numbness invaded the lower limbs, and the pain was aggravated. I learned that she had been treated by a Boston physician with some cancer remedy for over a year. Her case was complicated also by pregnancy, which made it all the more difficult to manage, even if there had not been any malignant disease. There was nothing really to do for her paralysis. She died on the 30th of September.

6. TREATMENT OF POTT'S DISEASE.

I propose, under this heading, to present a few cases representing different types of the disease, and will leave the cases to speak for themselves. It will be seen, however, that the details of treatment are very simple, *viz.*, to secure good fixation of the column, to prevent an increase of the deformity, and to rely upon exercise and out-of-door life as much as possible.

Case XII.—A gentleman, aged thirty, was referred to me December 13, 1894, by Dr. M. Allan Starr. He reported that for five years he had walked peculiarly and had been awkward in his gait. His friends had observed a wasting of the limbs. In the spring of 1894, he had typhoid fever, and while convalescing complained of a soreness in the iliac fossa, left side. He made a good recovery, and it was not until within three weeks prior to his visit to me that he complained of pain in the back and pelvis. The pain was most marked in the pelvis, and especially on the right side. Riding in a wagon of any kind added to his discomfort. If he walked about he was careful to avoid concussion. He presented a well-deformed antero-posterior curvature of the spine, from the mid-dorsal vertebræ to the sacrum; was tender to pressure, and concussion induced pain. His abdomen was retracted a good deal and he stood awkwardly, complaining that he could not "straighten up" well. There was little tenderness in the iliac fossa, left side, but no tumor. His thighs were weak, but the reflexes were not exaggerated.

I made a diagnosis of osteitis of the vertebræ, probably tuberculous in nature, and employed the cautery, and immediately after this some adhesive strips over the bosse. Advised him to have a plaster of Paris corset made if he did not get prompt relief. On the next visit, about a week later, I made him a plaster of Paris corset and applied it within a few days thereafter. January 8, 1895, he had no pain in the back, walked quite erect, and felt much improved. February 17th, was quite straight, had had no trouble for a month or more, wore the corset with comfort, attended to his duties, that of a groceryman in a small town in New Jersey, and had been free from pain or annoyance. I saw very little of him from that date, but had a report from him on the 7th of February, 1896. From this I learned that he was quite well and was cured.

Case XIII.—*Dorsal Pott's.*—A lady, aged thirty, was placed under my care November 3, 1887, by Dr. Boyd of Savannah, Ga. Her history was a very long one, extending over two or three years. She was treated for rheumatism, for uterine disorders, etc., etc. It was not until she came under Dr. Boyd's care that a diagnosis of Pott's disease was made. I attempted to fit her with a Taylor posterior spinal assistant, but she could not, for some reason, get accustomed to it; did not get the necessary support to enable her to walk well, although I made special efforts to get her properly fitted, and the apparatus seemed to me to meet every indication. After two weeks' trial I abandoned the brace altogether and applied the plaster of Paris jacket, cut down for a corset. The bosse, which was rather prominent, diminished a little on suspension in the swing. A good fit was obtained, and she went home on the 1st of December, standing the trip very well. A report by letter on the 17th of February, 1888, was encouraging, and a report from the doctor in April was confirmatory of the good result thus far obtained. The corset failed to give her the support after six months, as it had broken in one or two places, so she returned on the 29th of August, 1888, for further treatment. I made an attempt to fit her with the posterior spinal assistant again, but she was with difficulty induced to wear it, and was anxious to have the plaster corset renewed. We persisted, however, in the use of the apparatus, and she returned to her home at the end of a month. The reports were not so satisfactory during the next twelve months, and in the latter part of August, 1889, she returned, having spent several weeks at the Hot Springs in North Carolina. She had been bedridden for eight or nine weeks, and was thoroughly dissatisfied with the steel brace. A few weeks prior to her return there developed a fulness in the upper portion of the left thigh. I found a good-sized abscess, which was undoubtedly spinal. It was aspired, and seventeen ounces of pus withdrawn. During the two weeks following this I made three or four jackets before I got one at all satisfactory. About three weeks after the first aspiration I repeated the procedure, and withdrew thirty-six ounces of pus. Two weeks later thirteen ounces of pus was withdrawn and three and one-half ounces three weeks later. About this time the sac was pretty thoroughly empty and I kept the walls closely adherent by means of strips of rubber plaster. At the end of a month the sac had partially refilled and I aspirated again, getting this time three and one-half ounces. Shortly after this she returned, very much improved in every respect, and able to walk much better.

I saw her again February 21st, 1890, about two months after the last aspiration. She favored the left limb a little in walking, but I failed to detect any fluctuation in the iliac fossa, or on the outer side of the thigh. Her health improved and she became much more active, but it was not until March, 1892, that I detected a little fluctuation on the outer side of the thigh, in the site of the old abscess. Two ounces of pus were withdrawn and again on the 18th of April about one-half an ounce. Dr. Boyd wrote me in June, 1892, that he had succeeded in removing about four ounces of thick, shreddy pus. He thought at this time that she was developing pulmonary tuberculosis, but she went to the mountains and her health improved, the cough disappearing. I did not see her until the spring of 1894, when she seemed so far recovered that I urged her to remove the corset at night, but she objected to this on account of a dread of the return of the disease, so at this time I made a wood corset, after which there was no relapse of any kind, and during the year 1895 she continued to wear this support without any interruption. The latter part of 1895 I induced her to dispense with the wood corset and wear an ordinary corset, which I had had made especially to fit her back, and which she wore night and day. She came to the city in September, 1896, in order to have massage, and to "learn how to sleep" without the corset.

On October 17, 1896, I had Dr. E. G. Janeway in consultation, and he was unable to find any pulmonary lesion. There had been no recurrence of the disease. This, to me, had been a most interesting case, as it presented features at times that seemed almost beyond relief. The patient herself was very eager to follow the instructions closely, and the disease, I am sure, has undergone complete resolution. She wears an ordinary corset by day, and none at night, is able to attend to her household duties, can travel at will, and presents really very little deformity. The upper portion of the body seems to have developed and the deformity to have markedly receded. I have presented this case in detail to demonstrate what can be done by careful and repeated aspirations where the abscess is suitably situated, as well as the efficiency of a good splint to the back. She has been under my care, with only one interruption, from 1887 to the present time, nearly ten years.

I want to lay before you a case where the abscess was treated differently, and where the result promises to be equally good:

CASE XIV.—A gentleman, aged thirty, was brought to me for treatment on the 11th of September, 1889, by Dr. Glassford. He had complained for two or three years of his back, and during the winter of 1890-1891 an abscess appeared in the right loin. At the same time a second abscess appeared to the left of the spinous processes of the third and fourth lumbar vertebræ. Both were open, and when I made an examination there was a slight bosse in the dorsal-lumbar region, with a lameness affecting the right hip. I treated him by means of a plaster of Paris corset. His physician attended to the abscesses, kept them well drained and thoroughly aseptic. He has come to me from time to time for a new corset, and I think I have made him five altogether. He has attended to his business throughout. Quite recently he called and I found his general condition very good, he reporting that the sinuses were discharging a little, but that he had learned to take care of them, with the assistance of the doctor, and that his back gave him little or no trouble.

CASE XV.—A gentleman, aged thirty-one, was referred to me by Dr. Battle of North Carolina, November 7, 1895. For several years prior to this date he had suffered occasionally from a pulmonary tuberculosis involving the upper portion of the left lung, but under the influence of good air and hygiene, the process seemed to have been finally controlled. During the early fall he suffered much from lumbago, finding that he was unable to ride or to get about with any degree of comfort. The pains became quite severe, and at the time I saw him there was a marked kyphosis in the dorsal-lumbar region, the apex being in the lumbar. The pains were referred to the posterior aspects of the thighs. He was unable to stand erect, and it was difficult for him to get into an easy position. I applied a light plaster of Paris jacket as he lay prone between two tables, and from this jacket made a wood corset, which, after some little alterations, became quite tolerable. He went south the middle of December, 1895, bearing the trip well, and after a month the improvement was very marked. Toward the end of January he had a recurrence of his pulmonary symptoms, general condition grew worse, and early in February developed tubercular meningitis, from which he died on the 10th.

I have reported this case in order to bring out more prominently the importance of an early diagnosis, especially when the disease occurs in a patient already the victim of pulmonary tuberculosis. The necessary impairment to health, by reason of long suffering and anxiety, is decidedly in favor of a recurrence of pulmonary symptoms. After the deformity has presented itself, and after many weeks of suffering, one cannot expect to accomplish much by any treatment, but even in a case as desperate as this, the relief from a good fitting corset was most pronounced.

The remaining cases which I shall present illustrate the effect of immobilization in cases of Pott's disease where compression paraplegia exists.

CASE XVI.—A gentleman, aged forty-eight, was referred to me by Dr. E. G. Janeway, on the 3d of October, 1895. The doctor himself had made a diagnosis of Pott's disease a day or two before he came under my observation. The history was that all of the family had died of tubercular diseases, although he himself had been quite well and active in business, up to the invasion of the present disease, with the exception, perhaps, of pneumonia, some twenty years ago, which affected the left lung, and which was followed by pleuritic adhesions. In the fall of 1894, while returning from Europe, he suffered from what he described as "body pains." These pains were confined to the pectoral muscles and the ribs, but they were not very severe, and did not cause him much annoyance. On reaching home they gradually disappeared, and in February, 1895, they returned with a little more severity. One night, about the middle of March, he had a very sharp attack of pain, attended with fever, and he "ached all over," being treated for *la grippe*. At the end of three or four weeks he was sent south, but the temperature was exhausting, and he remained only a month, obtaining no relief whatever. The pains at this time were griping, and were below the mammary region on each side. He sought relief at the Hot Springs of Arkansas, and took a full course of treatment, but without effect. Soon thereafter the pains began to assume a girdle-like feature, and he found that he could not laugh or sneeze without pain, and was compelled to lie upon his back most of the time at night. He took to exercises of various kinds, in order to "work his rheumatism off." Later he sought relief at an "osteopathic" institution in Missouri, and left unimproved. In the latter part of August he had at his home an attack of what was called pneumonia, or pleurisy, and was in bed for a few days, at which time he was examined by distinguished surgeons, who differed as to his disease. One especially, of world-wide fame, pronounced the disease tubercular, while another pronounced it rheumatism or gout, and, as the latter was a medical man, his advice was taken. He urged dumbbells and exercises. An orthopedic surgeon is reported to have pronounced his case Pott's disease. He finally went to a sanitarium in the northern part of this State, and two weeks after beginning treatment began to feel a peculiar sensation in his lower limbs, and a tingling in the thighs. The spinal pains increased in severity, so he came to the city and consulted Dr. Janeway.

I found a deformity involving the eighth, ninth, and tenth dorsal vertebræ, exaggeration of the patella tendon reflexes, a typical spinal gait, with pains in the lower part of the back and thighs. With the history which he gave and with this cursory examination, I had no difficulty in confirming Dr. Janeway's diagnosis. He was very desirous of getting something that was light, so I made him a wood corset. In fact, I made him two or three wood corsets, but insisted on the recumbent posture and employed the cautery and potassium iodid. The wood corset was not satisfactory, and in December I abandoned this and made him one of plaster of Paris. The first one did not fit well, so I made a second, and he began to improve from that time forth. The subsequent notes are but a record of continued improvement; from a helpless individual, he became quite active, and now attends to business, going from one city to another without inconvenience. I occasionally see him when it is necessary to make a new corset, but these articles last a long time, and hence there is very little active treatment.

Case XVII.—A gentleman, aged twenty, was placed under my care May 30, 1892, by Dr. L. M. Yale. In 1884 he first showed signs of Pott's disease, and came under Dr. Yale's care two or three months later, when a plaster of Paris jacket was applied. He lived at some distance from the city, and the jackets were not renewed as frequently as the doctor desired. In the spring of 1891 he showed signs of weakness in the limbs, and his gate was distinctly ataxic. At this time he was treated in Boston, where the opinion was given by a most excellent surgeon that his ataxia was not due to compression myelitis. It is fair, however, to state that this gentleman, after observing the patient for a month or two, changed his opinion. In view of this apparent uncertainty, the patient became discouraged, and at a time, too, when his paralysis was increasing. At the time I saw him he could barely walk a few steps. He could lie on the couch, however, and move his limbs from side to side and over small ranges, but the muscles were very weak. All the reflexes were enormously exaggerated. The deformity of the spine was not great, and a Taylor brace, which seemed to fit him very well, was deemed quite efficient. I applied a plaster of Paris jacket, with head spring, made free use of the cautery, and gave potassium iodid in increasing doses. By the time he really came under treatment, June 10th, the paraplegia was about complete. Treatment was continued at his home by the family physician, who was most painstaking, and who carried out every instruction to the letter. Reports were received from time to time which indicated a marked improvement. I saw him on the 20th of April, 1893, after about eight or nine months' treatment. All of his muscles in both lower limbs responded well to voluntary efforts. He moved his limbs about without tremor, the reflexes were not very much exaggerated, and he could stand without any assistance, but I did not prolong the examination, for fear of a recurrence of symptoms. The improvement has continued up to the present time. I have made for him several plaster jackets and two or three wood corsets. During the last year he has been going about, has ridden a bicycle on one or two occasions, and has suffered no relapse. Quite recently I have made an examination, to find his return of power about complete. He is wearing a convalescing jacket. From time to time he is indiscreet in the amount of exercise, but a two or three days' rest is sufficient to bring about complete restoration.

SCARLATINIFORM ERUPTIONS FOLLOWING OPERATION OR TRAUMATISM.

By FRANCIS R. PACKARD, M.D.,
OF PHILADELPHIA.

My attention was first directed to this subject by the occurrence of two cases in the wards of Dr. John Ashhurst at the Pennsylvania Hospital. I am indebted to him for permission to refer to them.

Case I.—A. M., white, female, aged 2½ years. Necrosis of the metatarsal bone of the great toe. Two days after admission the diseased bone was removed. Twelve hours subsequent to the operation her temperature began to rise. It reached 105° F. twenty-four hours later, when a rash appeared, which was universal, bright scarlet, and not punctated. The throat was very red and sore and the tonsils swollen. There was considerable doubt as to the diagnosis, but on the second day after its appearance the rash disappeared coincidently with a rapid decline of the temperature to normal. There was no desquamation.

CASE II.—W. H., white, male, aged five years. Empyema. His illness dated back four weeks prior to admission. Sixteen days after his entrance to the hospital the chest cavity was opened and drained (Estländer's operation). The patient did perfectly well until the fourteenth day after operation, when his temperature went up to 103° F., the pulse became very rapid, and a faint, universal erythematous flush made its appearance. His throat became much reddened and very sore, and his tongue presented the typical "strawberry" aspect. He was promptly isolated. On the third day after its appearance the rash disappeared without any subsequent desquamation. There was no albuminuria. The case did well, and went on to recovery without further incident.

In neither case could any history of exposure to scarlatinal infection be found, although diligently sought for.

We see here two instances of scarlatinoid eruption following a surgical procedure, and apparently having a direct relation to it. In each instance the case ultimately proved not to be scarlatina, but not until there had been sufficiently suspicious symptoms presented to render the diagnosis very doubtful, and to throw a very heavy responsibility on the shoulders of the attending surgeon. No surgeon would knowingly omit any precautions which would prevent an outbreak of scarlatina in his wards, nor at the same time would he be willing to expose a child who might not have scarlatina to the risk of sending it into an isolation ward where it might be possible for it to contract the disease from other patients.

The cutaneous phenomena which so frequently manifest themselves after the performance of a surgical operation, or the reception of a wound, resemble scarlatina so closely that the name "surgical scarlatina" has been coined to describe them. In truth, many eminent authorities have held that all such eruptions should be considered as symptoms of true scarlatina, and that the patients should be isolated and treated as the subjects of that disease. This opinion is especially prevalent among English surgeons, and numbered among its supporters are Sir James Paget and Dr. Goodhart. On the other hand, many equally prominent practitioners can be named who hold that if scarlatina does occur in a patient who has been the subject of recent operation or traumatism, it is to be regarded as a mere coincidence, and that the numerous cases of scarlatinoid eruptions which have been reported are merely transient erythemata and of no particular significance. They claim that the term "surgical scarlatina" is a misnomer and should be abolished, as, if the disease does occur under such circumstances, it has no relation whatever to the surgical condition.

In 1887 Albert Hoffa, a German writer, attempted to make a definite classification of the rashes which occur under such circumstances.[1] He divides them into four classes, as follows:

1. Those which are due to vaso-motor irritation; chiefly seen after operation on parts which have an abundant nerve supply, and occurring a few hours after operation. They resemble an erythema, or sometimes an urticaria, and disappear a few hours after their appearance. Under this head he places puerperal scarlet fever.

2. He terms the second class the "toxic erythemas." They have no prodromal symptoms, appear usually after a lapse of twenty-four hours, or as late as forty-eight hours, after operation, are accompanied by much febrile and usually some gastric disturbance. They generally present themselves as a diffuse redness, or as large isolated patches of redness with clear interspaces, appearing only on the body and extremities, and vanish in twenty-four hours without desquamation. These are the result of absorption of wound secretions, such as fibrin-ferment. They are analogous to the eruptions caused by the absorption of such drugs as carbolic acid and corrosive sublimate, or to the ingestion of antipyrin, copaiba, etc.

3. This is the class of infectious erythemas in which the eruption is but the indication of a general septic infection, and in it are included the eruptions of pyemia and septicemia. They may be erythematous or urticarial; may be diffused or in isolated patches. The eruption is sometimes petechial, sometimes pustular; sometimes it closely simulates the rash of scarlet fever. These eruptions are attributed to embolism of the capillaries with micrococci.

This classification is so simple and so eminently practical that I shall follow it in my endeavor to analyze and classify such cases as I have been enabled to gather which have been of such a nature as to cause doubt as to a true diagnosis. It should be noted first, that scarlatina is practically the only one of the eruptive fevers that has been brought into prominence in connection with traumatic conditions.

Sir James Paget, in his address on surgery before the British Medical Association in 1862, mentioned the case of a boy, who, three days after the operation of lithotomy, developed a vivid red eruption at the site of the wound and went through a typical attack of measles. In the report of the Evelina Hospital for Sick Children[2] there are notes on two outbreaks of measles among the surgical cases in the wards. The first series of cases, numbering eight in all, were clearly traceable to infection from a nurse. Six of the eight patients had recently undergone surgical operations; one had a suppurating hip-joint, and in only one was there no inflammatory nidus. It is stated that these were the only cases which occurred among some fifty children, though no statement is made as to whether any of the children who escaped contagion may not have been the subjects of operation. The second series numbered five cases, all traceable to one of their number, a boy admitted with "fits," who presented symptoms of measles a few hours after his admission. The four cases arising from this, developed—one in a case of phthisis, one in a case of necrosis of the tarsus, one in a case of pustular eczema, and the other in a boy who had been the subject of a lateral lithotomy three weeks before. From the record of these two outbreaks, Dr. Goodhart infers that a larger experience will prove that measles has the same tendency as scarlatina to develop in these conditions, but being less widely spread and less active in its contagious properties, it is not so often seen.

[2] "Guy's Hospital Reports," vol. xxiv, 1879.

These are the only instances I have been able to find of any eruptive disease other than scarlatina following upon trauma or operation so as to exhibit in any way a relationship between the occurrence of the exanthem and the injury, and I am not inclined to think that any of these cases indicated anything more than a coincidence in their development. Civiale, who appears to have been the first to call attention to these traumatic eruptions, says that papulo-macular or petechial eruptions are not infrequently met with in patients who have undergone lithotomy. He makes no mention of a rash in any way resembling scarlatina, or any other of the exanthemata.

As regards the development of scarlatina under such circumstances, we have the reports of numerous cases in which not only did the patient present symptoms of scarlatina himself but communicated it to others; and, in addition, a large number of cases of so-called "surgical scarlet fever," in which the diagnosis of scarlatina could not be rendered so positive. But no one will dispute the importance of making an early and absolute diagnosis. When one considers what an outbreak of scarlatina in a hospital means, he certainly will run no risk of incurring it through an error of diagnosis.

The question naturally arises as to why scarlet fever and not the other exanthemata should be predisposed to, and why it should be simulated under such circumstances; and here we are confronted by the fact of the frequency of scarlatiniform eruptions in conditions in nowise allied to scarlatina. Thus, the various drug rashes (copaiba, belladonna, antipyrin, quinin, etc.), are in most instances of the nature of an erythema, and many cases are recorded in which they were confused with the disease whose skin lesion they so closely resemble. Scarlatinoid eruptions have been reported as having followed such trifling disturbances as that caused by the passage of a sound, or the administration of an enema. Frequently red rashes, usually, however, localized in area, appear as the result of reflex disturbance in uterine or ovarian disease, or at the menstrual period. Of course, the explanation of this is to be found in the fact that they are all practically embraced within the first two classes mentioned by Albert Hoffa (*op. cit.*); that is, they are either the result of direct vaso-motor irritation, or, as in the case of the drug rashes, are secondary to the absorption of some substance which acts on the vaso-motor nervous system in such a way as to disturb its equilibrium. It would seem that the most common source of error in the diagnosis of cases of this character has been that the rash has alone been considered to be the diagnostic feature, and the other symptoms of scarlet fever have either not been sought for, or, if not present, the case has been ranked as scarlatina of an atypical type.

Dr. A. O. Blackadder[1] emphasizes the fact, so often overlooked, that "the mere presence of a scarlatinal rash, going on to desquamation and associated with pyrexia, does not of itself warrant the diagnosis of scarlet fever." Considering the variety of conditions which give rise to scarlatinal rashes, it would seem unwise to regard as the most important and characteristic feature of a disease that symptom which, above all others, is most frequently simulated. Systematic writers notice the occurrence of *scarlatina sine angina* and of *scarlatina sine eruptione*, thereby demonstrating the liability of the disease to variation as regards its most prominent symptoms.

Paget[2] regarded all these scarlatiniform eruptions associated with pyrexia and following surgical procedures, as true scarlatina. He held the view that the occurrence of scarlatina after operation was not a coincidence, as, if it were, we would find a corresponding number of cases among surgical patients who had not been operated upon. He never in his private practice saw scarlatina supervene in a surgical case which had not been the subject of recent operation, whereas, the year previous to the publication of his lectures he saw six cases following operations in his private practice, had notes of four others, and had heard of many more. He states as his opinion that there was something in the consequences of a surgical operation which made the patient peculiarly susceptible to the scarlatinal infection, and he held that with this susceptibility of the patient the disease underwent certain modifications, which accounted for the obscuration of the diagnosis in so many of the cases.

[2] Clinical Lectures on Surgery.

E. C. Stirling,[1] after a most exhaustive investigation of the subject, affirms that "there occurs sometimes after wounds and injuries what may be called a simple surgical erythema, often closely resembling scarlet fever but independent of any connection with that disease. Other eruptions of different type may occur under like circumstances." He says scarlatina occurs also in such conditions, but whether it should be regarded as more than a mere coincidence he thinks is still *sub judice*. He recommends that all such cases should be isolated, as an absolute differential diagnosis is in the majority of cases almost impossible. Goodhart (*op. cit.*) states that "there is no room for doubt that scarlet rashes after operation at the Evelina Hospital have mostly been veritable scarlet fever." He says distinctly that he does not regard all red rashes following wound or operation as scarlatinal, but that experience shows that they are mostly such, and hence should be isolated. The twenty-five cases, however, which he commented upon, all presented a definite history of infection, and when removed to the fever ward where patients with scarlet fever were confined none of them contracted it. All of them presented other characteristic features in addition to the rash. Dr. Goodhart holds that any local nidus of inflammation suffices to increase the susceptibility of a patient to scarlatina, and that it is not necessary for a traumatism or an operation to have occurred recently to increase this susceptibility. Hoffa (*op. cit.*) thinks that there is no doubt that surgically wounded patients manifest a predisposition to contract scarlet fever. His view is that the disease enters the system through the wound, and in support of this he cites cases in which the eruption began at the edges of the wound and gradually spread from there over the body. He differs from Paget, who thought that the poison lies dormant in the system of the patient at the time of the reception of the wound, and that the patient might never manifest the disease if his vitality had not been impaired by the latter. Against Hoffa's view might be stated the fact that undoubted scarlet fever has been reported as occurring in cases where the repair of the wound has run a healthy course throughout.

J. Hendrie Lloyd[2] reported a case which was undoubtedly one of true scarlet fever, as it gave rise to an epidemic. The wound was a trephining one of the skull, and the eruption made its appearance on the abdomen and thighs. In Henoch's case,[3] which also was one of true scarlet fever, the operation was the opening of an abscess in the pectoral region, and the eruption began on the face, arms, and inner surfaces of the thighs.

In contradiction of Paget's theory of the occurrence of the disease being a result of impaired vitality we may cite the numerous cases which have occurred after very slight disturbance of the organism. Thus the opening of an abscess rarely depresses the vitality of the patient. J. Walter Browne[1] reports the occurrence of true scarlet fever, proved by its communication to other patients, in a man whom he had circumcised, an operation certainly not calculated to greatly impair the vitality.

An analysis of the reported cases has been rendered difficult by the various manners in which they have been reported, and because so many of the cases said to have been of true scarlet fever were simply judged to have been such by the appearance of the rash, and have been reported without reference to the absence or presence of other diagnostic symptoms of the disease.

As regards the nature of the injuries or operations which are followed by scarlatiniform eruptions or scarlet fever.—From the following table it may be seen at a glance that the nature of the injury or operation has but little if anything to do with the development of the eruption. All of the abscesses in the list were probably tuberculous, save two, as they communicated with diseased bone. Of the two exceptions, one was an ischiorectal abscess, the other an abscess over the pectoralis major muscle. Lithotomy stands high on the list, and attention may again be called to the fact that Civiale mentions the development of eruptions after this operation. The cases here included are all such as were regarded as true scarlet fever or as "surgical scarlet fever" by those who reported them :

Opening of abscesses, 16; lithotomy, 13; circumcision, 8; burns, 7; staphylorrhaphy, 5; tracheotomy, 4; tenotomy, 4; osteotomy, 4; sequestrotomy, 4; harelip operation, 3; bruise, 3; removal of diseased tarsus, 2; amputation of thigh, 2; plastic operation for webbed fingers, 2; opening of sinuses, 2; lacerated wound, 2; removal of lipoma, 2; scalds, 2. Of each of the following there was one case reported: Supernumerary toe (plastic), aspiration of abscess, herniotomy, ovariotomy, excision of elbow, amputation of arm, resection of knee, ligation of varicose veins, Syme's operation (disease of tarsus), tonsillotomy, removal of exostosis from tibia, removal of cysts from neck, resection of hip, operation for encysted hydrocele, fracture of femur, puncture of cyst, abrasion of arm, excision of hemorrhoids, operation on septum nasi, incision of empyema with drainage. Total, 105.

[1] *British Medical Journal*, vol. ii, p. 692, 1895.

As regards the age of the patients.—The age of the patient was stated exactly only in seventy-two of the above cases. The oldest patient was a woman of twenty-six years, the youngest a child of twenty-one months. But five of the seventy-two were twenty years old or upwards. The average age was six years and four months. Some have regarded the youth of the patients as significant of these eruptions being truly scarlatinal, because of the much greater frequency of occurrence of scarlet fever during childhood. It must be remembered, however, that a child's nervous system has not attained the equilibrium possessed by that of the adult, and that vaso-motor phenomena are consequently more easily induced and are of more striking character than they are in the adult. It is probable that the majority of these cases come under the first class of Hoffa, and must be regarded as vaso-motor phenomena.

Sex.—It is a curious fact that although we might have expected, from the greater susceptibility of their nervous systems, to find the number of females exhibiting these phenomena greater than the number of males, the contrary is true, for of 104 cases in which there is a record of the sex, 61 were males and 43 females. Of course, there is no difference in the susceptibility of the two sexes to scarlet fever.

The history of infection, or of non-exposure, presented by such cases.—In some of the cases recorded, which afterwards proved themselves to be undoubted scarlet fever, it was impossible to find any source of infection. In Lloyd's case (*op. cit.*) he was unable to trace any history of exposure whatever, the ward in which it occurred being new, somewhat isolated, and having never contained a case of scarlet fever before. The patient had not been exposed to infection from without. There is also the celebrated case of Surgeon-Major Ffolliott of Peshawur,[1] in which a private in the British army in garrison in India was injured by a powder explosion, and four days later developed a bright scarlatiniform eruption with rapid pulse and high temperature. The medical officers pronounced the case one of scarlet fever. Anent this case, Sir Joseph Fayrer made the statement that scarlet fever was so rare in India that many hold it is not seen at all. He had seen but two cases and these were distinctly traceable to a box of infected clothing sent out from Europe.[2]

J. Walter Browne (*op. cit.*) reports an interesting series of cases in this connection. A man admitted to his ward, and circumcised the day of admission, thirty hours after operation developed a typical attack of scarlet fever and died in seventy hours. It transpired that during the two weeks previous he had been daily visiting a friend who was suffering from scarlet fever. A girl, whom his assistant dressed after having earlier in the day attended upon the circumcision case, developed scarlet fever in sixteen hours. A child that was admitted to the ward with a lacerated wound of the leg, and placed for three-quarters of an hour in a bed next to that occupied by the girl mentioned, six hours after admission, developed headache and vomiting and died in fifteen hours without the appearance of the rash. *Post-mortem* an abundant purpuric rash appeared. Here the disease seems to have manifested an extreme degree of contagiousness and malignancy. He also reports an isolated case of a healthy child with a harelip, who, sixteen hours after operation developed a rash and died. It had been exposed three months previously to operation.

Immunity.—The question arises whether these scarlatiniform eruptions manifest themselves as readily in those who have previously had scarlet fever as they do in those who have never had the disease; also, whether the occurrence of the traumatic rash renders the patient any less liable to subsequent infection. Scarlet fever is a disease which is particularly inapt to occur twice in the same individual, hence the question of immunity would seem to have an important bearing on the nature of these eruptions. The records concerning this point are, unfortunately, very scanty. H. W. Page[1] reports a case of undoubted scarlet fever occurring in a man who had had two previous attacks. It was a genuine case of the disease, as he communicated it to one of his nurses. He had had some old sinuses in his groin slit up five days previous to the appearance of the eruption. Mr. George May[2] reports what appears to have been genuine scarlet fever following a lacerated wound of the scalp in a boy who had previously had the disease. The only anomalous symptom of the boy's second attack was the absence of sore throat; otherwise the case was typical. Of course, with such scanty data, no definite conclusion can be drawn. Mr. Murray,[3] however, in reporting an outbreak of scarlet fever in the Pendlebury Children's Hospital, states that at the time of the outbreak there were twenty-seven children in the ward, twenty-three of whom had wounds, while four had not. Five of the patients with a wound had previously had scarlet fever; none of the cases without wounds had ever had it. Only one of the patients without a wound contracted the disease.

Does an operation or a traumatism increase susceptibility to scarlet fever?—Paget (*op. cit.*) thought that it does, and produced records from his case-book to prove it. Goodhart, as we have seen, thought that any inflammatory focus in an individual rendered him more apt to contract scarlet fever. Mr. Murray's series of cases, referred to above, would seem to bear out the view that susceptibility is increased by a wound or an operation. Paget, in reporting the case which we have cited, raised the question as to whether it is justifiable to operate on a patient who has been even remotely exposed to the contagion of scarlet fever. The man upon whom he operated had two nurses in constant attendance, and they were equally exposed to contagion. One of them contracted the disease. The other nurse had never had scarlet fever, and two weeks later Paget removed one of her breasts for an adenosarcoma, yet she never manifested any symptom of the disease. He questions whether it was right for him to operate when he knew she had been thus exposed. J. A. Lea[1] reports a case of abscess of the leg from necrosis of the tibia. The patient was a man aged thirty-nine years. A few days after the operation his temperature rose to 104° F., and a scarlet eruption appeared, which went on to desquamation. He had albuminuria, but no sore throat. It was shown that one of his children had just had scarlet fever, and subsequently several more of the children developed it, but the surgical patient was the only adult among a number who were equally exposed who manifested any symptom of the disease.

The relation which the treatment and behavior of the wound bears to the development of such eruptions.—The earlier writers on this subject wrote at a time when the antiseptic treatment of wounds was just coming into vogue, and had not of course reached its subsequent perfection of technic. Goodhart laid stress upon the fact that the principles of antisepsis, as at that time laid down, had been strictly carried out in all the cases reported from the Evelina Hospital. Stirling emphasized the statement that if the theory of the absorption of the scarlatinal poison through the wound is correct, we should find a most notable diminution in the number of cases when the antiseptic treatment would be more universally adopted. This diminution has not occurred. Fully as many cases are seen at the present time, when the aseptic treatment of wounds is so thoroughly understood and practised, as at the time when he wrote (1879). It might be suggested that some of the rashes occur as the result of the use of the drugs employed in procuring this asepsis; but even if we exclude some cases on these grounds, we have epidemics, such as Lloyd reports, where the wound was rendered as sterile as possible, and where the disease proved itself true scarlet fever, so that there was no question of any drug-poisoning. Of course, the occurrence of pyemic or septicemic rashes, the result of invasion of the organism by septic material in the wound, is not to be considered as affecting this statement, as we refer only to the occurrence of genuine scarlet fever, or of the scarlatiniform erythemata.

As regards the behavior of the wound, we can only say that it appears, in the vast majority of cases, to bear no relation to the rash, or to infection with true scarlet fever. In Lloyd's case the wound pursued a healthy course. Occasionally, as in J. A. Lea's case, the wound assumes a phlegmonous and unhealthy appearance. As the occurrence of any pyretic condition would in most cases somewhat disturb the process of healing, we must distinguish the unhealthy appearance of the wound resulting from an intercurrent febrile attack from a bad condition of the wound causing such an outbreak.

Variations in the course of true scarlet fever occurring under such circumstances.—We would naturally expect to find the disease undergoing some modifications in its course if it occurred in a patient suffering already from a wound, but the question we desire to answer is, Is there any constant variation in scarlet fever in these conditions which will always be present when the disease follows traumatism? To this we must answer in the negative. "Surgical scarlet fever" possesses no distinctive feature; it varies with the greatest irregularity, or sometimes varies not at all. Some have held that the period of incubation of the surgical form is shortened, but it has been proved that it varies from twenty-four hours to six days, and averages about the same as that of ordinary scarlet fever.

The rash presents, as might be supposed from it always being mentioned as the characteristic of "surgical scarlet fever," the same features as the ordinary scarlatinal rash, varying, as it does, occasionally, but as a rule appearing as an erythematous, punctate flushing, which disappears in three days by scaly desquamation.

One curious fact is that even when the disease has definitely proved itself to be scarlet fever, there has been a marked tendency to an absence of sore throat, or when it has occurred it has been mild, as in Lloyd's case.

Medical Men Volunteering to Fight the Plague.—A call has been issued to army medical officers in England for volunteers to go to Bombay and assist in suppressing the plague. It is meeting with prompt response.

[1] *British Medical Journal*, February 15, 1879.

MYCOSIS OF THE TONSILS AND ADJACENT PARTS.

By FRANK S. MILBURY, M.D.,
OF BROOKLYN;
LARYNGOLOGIST TO THE BEDFORD HOSPITAL AND DISPENSARY.

SINCE the first contribution to literature on the subject of mycosis of the tonsils and contiguous structures by Fränklel, in 1873, others have written more or less concerning this disease, yet information at this date in medical books or journals is meager, and little or nothing new has been elicited in the way of diagnosis or treatment. Various investigators have reported this affection as occurring in persons of all ages, ranging from twelve years to over sixty, although it is usually a disease of young adult life. Lennox Browne says that it "generally occurs in subjects living in damp, unsanitary dwellings and neighborhoods, and who exhibit want of cleanliness." This may in a measure be true, but I think the experience of others goes to prove that the disease is just as liable to be found among persons living among the best of sanitary surroundings and of most cleanly habits. I think it is generally seen in persons suffering from a general cachexia and from catarrhal affections, but the etiology of pharyngo-mycosis is extremely uncertain. No researches have as yet succeeded in tracing the origin of this disease, but there is a consensus of opinion that the leptothrix bacillus is the leading microbe found in the growth. Hypertrophied tonsils, atrophic rhinitis, mouth-breathing, etc., seem to predispose to the production of the disease.

According to writers on the other side of the Atlantic, mycosis is a rare affection, and in this country comparatively few cases are brought to the notice of the profession. In mycosis of the throat an accurate diagnosis is always desirable for its successful treatment, as there is a possibility of its being confounded with follicular tonsillitis or pharyngitis; and as the methods of treatment are so different it is very essential that the proper line of procedure be adopted at the beginning. Some affections may be successfully treated symptomatically, but mycosis cannot. One writer mentions dental caries as a possible cause of the disease. Microscopic examination will clear up any doubt as to diagnosis.

Local symptoms vary; sometimes nothing is felt; again, there may be a scratchy sensation, or a slight or severe tickling, producing cough, dyspnea, dysphagia, etc. In other cases inflammation, with pain and fever, is present, with the consequent constitutional disturbances. Asthma is sometimes present, and is quite persistent. The objective symptoms are spots upon the pharyngeal wall, the lingual, faucial, or pharyngeal tonsils, or on the anterior or posterior pillars, but apparently the favorite seat is upon the faucial tonsils.

I think Dr. Henry B. Hemenway describes this affection better than any authority I have seen, so I shall quote his words as follows: "These spots vary in color from white to cream yellow, but the former is the prevailing color. When upon the tonsils they are seen to grow from the crypts, are very tenacious, not easily torn off, and when removed by forceps are rapidly reproduced in the same locality, sometimes within twenty-four hours. Generally, the growth is in the form of filaments or tufts; sometimes confluent in a form of membrane. Normally, the mucous membrane around the fungus is natural in color. Mycosis is differentiated from diphtheria by its chronic nature; by less tendency for the fungus to spread; by absence of fever and symptoms of systemic disturbance—excepting when accompanied by tonsillitis; by absence of the diphtheritic odor; by absence of pain, and by the form of the fungus. When in the membranous form it does not come off as a membrane, but breaks in pieces. When removed it sometimes leaves bleeding spots, but the mucous membrane is not so much denuded as in diphtheria. In follicular pharyngitis the contents of the follicles are easily expressed. The calcareous concretions sometimes found in chronic follicular amygdalitis often project from the crypts and are also easily expressed. Although in follicular inflammations the accumulations frequently contain leptothrix threads, they are not composed of the filaments. The only sure way or method of diagnosis is by the use of the microscope."

This affection is not dangerous in any degree, but is very troublesome, owing to the peculiar liability of persons so affected to frequent acute inflammations of the tonsils and adjacent parts, and extension into the larynx. Dr. Hemenway states that "it may be implanted upon the nasal mucous membrane or in the lungs." The former is correct, but I believe the latter to be impossible. Certainly, no instance of this particular fungus being found in the lungs has been recorded, as far as I have been able to discover. At one time I made a note of a case discovered in the larynx, but have forgotten when or by whom noticed.

Many methods of treatment have been suggested, such as the local application of chemically pure lactic acid, bichlorid of mercury solutions, or alkaline solutions, (on the theory that the leptothrix germs thrive only in acid secretions), and of tincture of iodin, nitrate of silver, alum, tannin, permanganate of potassium, etc., but these agents in my hands have only given temporary relief, and like all other medicinal lotions have proved worthless as regards a permanent cure. Dr. John Dunn of Richmond, Va., claims good results from the use of permanganate of potassium. With all specialists the galvano-cautery alone, or the curette or forceps, followed by the cautery until the base of the trouble is reached, has proved the only means of complete eradication.

The following is a case in point:

Miss J., aged nineteen, accompanied by her family physician, called on me in October, 1891. The latter wished to ascertain why it was that he could not cure a case of follicular tonsillitis, which had been so much more obstinate than any before met with in his experience. The lady belonged to a wealthy family, and was herself large, very robust, and energetic. The sanitary conditions of her home were of the best, and all surroundings favorable to health and good nature. She was subject to frequent attacks of acute tonsillitis, and latterly to a slight cough and a very annoying scratchy sensation of the throat, which would not respond to treatment. Ocular inspection revealed considerable hypertrophy of both tonsils with numerous deep crypts filled with a whitish substance which I believed to be leptothrix. This supposition was confirmed subsequently by microscopic examination. I pronounced it a case of mycosis, and, the tonsils being so large, I believed that by excision I could get below the base of the trouble and thus effectually eradicate the disease. Tonsillectomy was therefore performed, but it resulted in failure, as the disease extended much deeper. I then concluded to use the electro-cautery. This was applied at intervals of from one to two weeks, fourteen times in all, before thorough eradication was accomplished. Up to the present date there has been no return of the disease.

During the last four years I have seen eleven cases of tonsillar or pharyngo-tonsillar mycosis in persons ranging from a robust condition to that of general asthenia. Some have been in families with good, and some in families with very bad, sanitary surroundings, and sanitation appeared to have very little to do with it. A majority of the patients were subject to recurrent acute tonsillitis or pharyngitis, and some had great hypertrophy of the tonsils, in which cases excision effected a cure. One patient, particularly, thirty-six years of age, who had suffered for years from tonsillitis and asthma, applied to me for relief. The nose was in excellent condition, but the tonsils were of enormous size and were mycotic. They were removed, and the asthma and tonsillitis vanished, never to return. Of course, I do not believe that the mycosis had anything to do with the asthma, as this must have been produced chiefly by the great obstruction in the pharynx which impeded free respiration.

The Superior Longevity of Women.—Of the fourteen reputed centenarians who died in England during 1896, eleven were women. Of the 188 persons who were declared at death to be over ninety years of age, 108 were women.

CLINICAL MEMORANDA.

HERNIA OF A SARCOMATOUS OVARY.[1]

By GEO. SEYMOUR, M.D.,
OF UTICA, N. Y.

Sarcoma of the ovaries within the pelvis at their normal location is comparatively rare. Cystosarcoma, fibrosarcoma, and round-celled sarcoma are more often mentioned than spindle-celled sarcoma; so that a spindle-celled sarcoma escaping when of small size through the internal ring, and developing outside the pelvic cavity proper, and retaining direct relation to the uterus by means of peduncular attachment may be regarded as exceedingly uncommon.

On the 15th day of November last I was requested to visit Mrs. D. to advise in reference to a swelling or tumor in the right inguinal region. She was forty-eight years old, mother of several children, the oldest twenty-five years, the youngest five years of age. She gave no history of miscarriage or menstrual derangement of any kind, and said that a small tumor had first appeared about two years before, had gradually increased in size without causing pain or discomfort, had disappeared when she was in the recumbent position during the first year of its existence, but had remained prominent both day and night during the past year. On examination I discovered the tumor to be somewhat sensitive to touch or pressure, with slight heat and redness of the surface, hard and irreducible. For two weeks previously it had caused some pain when she was in the standing or sitting posture. There was no vomiting nor obstruction to movements of the bowel. The appearance and location of the tumor led me to think it to be an inguinal hernia, possibly of incarcerated omentum, without strangulation. Dr. A. R. Simmons, who saw the case with me a short time after my first visit, concurred with me in the opinion that an operation for reduction of the tumor and relief of the patient was advisable. She accordingly went to St. Luke's Hospital, and on November 23d we performed an operation, the commencement of which was with the idea of dealing with an ordinary inguinal hernia not accompanied by intestinal obstruction.

After incision of the integument and tissues across the face of the tumor down to its sac, which was composed of layers of fascia and peritoneum, the mass was found to be attached to a large pedicle or ligament about four inches long and three-quarters of an inch in diameter, extending from the uterus within the pelvic cavity out through the internal ring to the under side and upper end of the tumor as it lay in the inguinal canal. The pedicle was tied with a strong silk ligature, cut off at about the junction of its outer and middle thirds, and the end of the portion left within sutured with catgut into and at the opening of the internal abdominal ring. A portion of the sac was ligated with catgut and excised. The tumor was ovoid in shape, four inches long, eight inches in circumference, and weighed five and three-quarter ounces. The wound was closed with silkworm-gut sutures, except at its lower part, and iodoform gauze left in the whole tract for drainage. At the end of six weeks from the time of the operation the large ligatures about the pedicle had passed out at the sinus and the wound was completely closed. Microscopic examination of the tumor by Dr. Stump, the pathologist of the hospital, proved it to be a spindle-celled sarcoma of the ovary.

---

[1] Abstract of paper read before the New York State Medical Society, Albany, January 28, 1897.

The woman is now in good health, and has neither direct nor indirect local or general disturbance of the pelvic organs. Menstruation has occurred twice since the operation in a perfectly normal manner.

THE SERUM-THERAPY OF DIPHTHERIA IN PRIVATE PRACTICE.

By A. C. HERMAN, M.D.,
OF LANSDALE, PA.

DURING the past spring and summer no less than thirty cases of diphtheria appeared in the town of Lansdale. Some of these were treated with antitoxin, while others received the older treatment. The results were so favorable to antitoxin that I am prompted to report them. I am now convinced that in all cases of diphtheria speedy and immediate cure will follow the early and proper use of this agent, and that no sequelæ or untoward complications need be feared. This declaration is made independently of any statement relative to the day on which the initial dose is or should be given. I wholly agree with the foremost authorities that the *early* employment of the serum is always most desirable. What I wish to state is, that the severity and prognosis of a case is not dependent, *per se*, upon the number of hours which may have elapsed since the appearance of the first symptoms, but upon the quantity and virulence of the toxins absorbed into the system, and the cell destruction of the vital organs caused by them. The wide difference between individual cases of the same epidemic of diphtheria, and between cases of different outbreaks is thus explained.

The best rule for treatment is to give the initial dose of antitoxin immediately after the diagnosis of diphtheria is made. In all doubtful cases it is best to administer it even if a positive diagnosis cannot at the time be reached. Professor H. C. Wood states: "There is no reason at present for believing that antitoxin in moderate quantities does any harm when the child has not diphtheria. When, therefore, any case presents the clinical aspect of diphtheria, antitoxin should be used at once." Dr. L. Emmett Holt, Chairman of the Committee of the American Pediatric Society appointed to investigate the results of the serum treatment of diphtheria in private practice, speaks of the action of antitoxin in the system as being two-fold: (1) It prevents further development of the specific bacilli; (2) it neutralizes the toxins already present in the system. If the deadly effect of the toxins upon the centers of vitality has already passed the line beyond which redemption is impossible, it is clear that at best antitoxin can simply somewhat lengthen life.

One point I wish to make prominent here is that carbolic acid, which is but feebly antiseptic except in strong solutions, is a powerful toxic agent in the human system. It is too irritant a drug to use in the preservation of antitoxin. I believe the failure to recognize this fact has resulted in deaths which were falsely charged, in part or wholly, against the antitoxin treatment. Trikresol, which is but feebly toxic, does not irritate the kidneys, while it is such a valuable antiseptic that but five-tenths of one per cent. is required to positively prevent contamination of the serum. All zymotic diseases necessarily have a most dire effect upon the vital organs; these need sustaining treatment, and it is as important to husband the patient's strength as it is to combat the disease. The following are a few reports in detail of my personal experience with antitoxin:

CASE I.—L. G., aged six years. The membrane covered all of the pharyngeal surface and extended into the larynx and trachea. It so impeded respiration that suffocation was imminent. The patient's sonorous breathing was audible from every part of the house. There was a most harassing cough. Prior to my visit she had had no treatment. The house next above and the second one below were under quarantine, and in each of these homes one child died. No antitoxin had been employed.

Sixteen years of practice, during which I had seen many cases of diphtheria, showed me that the case was a hopeless one. I was forced to the conclusion that no line of treatment hitherto advanced in this dread disease could save the patient, unless it was that of antitoxin, which, however, I had never used. A messenger was hastily sent for 2000 units (20 cc.) of antitoxic serum. During the afternoon of the same day 1000 units of the antitoxin was injected in the region of the groin, and on the following day I repeated the dose. The result was prompt and decided. As supplementary treatment, quinin, calomel, tincture of iron, and a liberal supply of whisky, was used. The convalescence was uneventful, the patient being discharged one week after my first visit.

CASE II.—Wm. G., aged fourteen, a member of the same family, was taken ill on the day his sister received her initial dose of antitoxin. His entire pharyngeal surface was early enshrouded with the diphtheritic membrane. He was promptly given an injection of 1000 units, which for the sake of prudence was repeated on the second day, although the throat was almost clear of membrane at that time. The patient rapidly recovered. In this case the additional treatment was confined to an astringent gargle, tincture of iron and quinin.

CASE III.—A. B., aged six years. This case appeared a few weeks after the foregoing. The appearance of the throat excited suspicion, but could not lead to a clear diagnosis of diphtheria. After employing the usual remedies with only moderate success for about six days, the entire pharyngeal surface was rapidly invaded by the characteristic membrane. The patient was promptly given an injection of 1000 units and all other treatment was discontinued, except small doses of tincture of iron. In this case I used a concentrated form of antitoxin, 4 cc., representing 1000 antitoxic units. The dose was repeated once. The result was the same as in the other cases.

CASE IV.—R. T., aged five years. This case was one of several in the same family, all of which, except this one, were very mild attacks and were not treated with antitoxin. The disease in this patient early assumed a most malignant aspect, the throat being literally full of the exudate. One thousand units of concentrated antitoxin was injected, and the dose repeated on the following day. The effect was again equally favorable.

At the same time, a brother physician had a patient, an only child, in a neighboring family, who was suffering from a most virulent attack of the disease. Encouraged by the foregoing results the physician borrowed my syringe, and with two doses of 1000 units each, successfully treated his case.

The dread that I always entertained of having this monster, diphtheria, invade my own home and community, has absolutely left me, as I am now firmly convinced that in antitoxin we have a remedy that is worthy of our entire confidence.

MEDICAL PROGRESS.

The Pathology of Multiple Sclerosis.—GOLDSCHEIDER (*Zeitschrift für Klinische Medicin*, B. xxx, H. 5, 6, p. 417,) has reported a case of multiple sclerosis terminaing fatally as a result of intestinal hemorrhage in the course of an attack of typhoid fever, and showing apparently the important part played by the blood vessels in the pathology of the spinal disorder. A girl, twenty-two years old, without neuropathic heredity, began to complain of a sense of heaviness in the legs, with difficulty in ascending stairs. Vertigo was present during the day, and on one occasion the patient fell, arising, however, immediately. On two occasions there had been vomiting. Drowsiness also manifested itself. On awaking one morning vision was obscured by tremor of the eyelids and hearing was dull. The impairment of vision and of hearing was greater upon the right side. On attempting to rise the patient fell. During the night there had been severe headache, much worse on the right side. The patient was well developed and well nourished. The face was flushed, the hands somewhat livid, the feet cool. No visceral disorder could be discovered. Marked nystagmus was present and was principally vertical. The palpebral fissure was narrow on either side. The left pupil was somewhat larger than the right; both reacted to light and in convergence. No ophthalmoscopic abnormality was detected. The patient complained of the movement up and down of bodies before her eyes. On lateral movement of the eyes the objects moved forward and backward. There was complaint of roaring in the right ear. Both auditory canals contained plugs of cerumen, the removal of which was, however, not followed by improvement of hearing. The upper extremities were ataxic, the right in particular, and this was also weakened. The right lower extremity also was ataxic and weak. The tendon-reflexes and the bone-reflexes in the upper extremities were preserved; the triceps-jerk was the more marked upon the right; the knee-jerk was exaggerated upon both sides, but there was no ankle-clonus. Sensibility was undisturbed. The cutaneous reflexes generally were enfeebled. The vesical and rectal functions were maintained. In the progress of the case the paresis of the right upper extremity increased. The uvular, palatal and pharyngeal reflexes were wanting. The tongue was protruded properly. The chin-jerk was preserved. Both deglutition and articulation were effected normally. The corneal and conjunctival reflexes were active. The sense of smell and also of taste was scarcely as acute upon the right side as upon the left. There was a conspicuous tendency to somnolence. In the course of the disease a sense of numbness in the right arm was complained of, and on examination it was found that painful and tactile sensibility was diminished in the right hand, the whole of the right arm, the right half of the back and chest, the right side of the face and the right half of the tongue. In slighter degree the sensibility of the right foot also was impaired; on the other hand, the disturbance was more marked in the right leg and thigh. The grasp of the hand was greatly enfeebled, and there was considerable difficulty in moving the right arm. The knee-jerks were still active on both sides. The cutaneous reflexes had become feebler on the right than on the left. Later, numbness and weakness, with ataxia and impairment of sensibility, appeared in the left lower extremity, and the head became tremulous. Symptoms of typhoid fever made their appearance, and death ensued in the sequence of hemorrhage from the bowel. *Post-mortem* examination disclosed, in addition to the lesions of typhoid fever, parenchymatous myocarditis, fibrinous pneumonia of the right lower lobe, pulmonary edema, nephritis, hepatitis, parenchymatous gastritis, and chronic diffuse interstitial encephalitis. On section, both brain and cord appeared remarkably firm. On transverse section through the upper portion of the pons, the vessels were seen to possess an unusually large lumen, and the surrounding tissues presented a grayish-red color. In the middle of the medulla-oblongata a similar grayish area was found. No gross microscopic change could be detected in the spinal cord, and bacteriologic examination yielded negative results. A number of the peripheral nerves examined were found to be normal. After preservation of the cord for several days in Müller's fluid an extensive area of degeneration in the cervical region became visible, extending forward to the posterior commissure, on the right to the median limit of the right posterior horn and backward close to the periphery. The area corresponded to the second and third cervical segments, and had a vertical extent of rather more than half an inch. After preservation for four months in Müller's fluid scrutiny of sections showed in the affected areas a morbid process arising from the vessels and leading to swelling of the nerve-fibers. Many of the medullary sheaths were thickened, and the axis-cylinders shared in the swelling. Some of the medullary sheaths, on the other hand, were reduced in size, and some of the axis-cylinders deprived of their myelin. These had evidently passed through the stage of swelling. In the dorsal region of the cord there existed a diffuse sclerosis of considerable degree, with degeneration and atrophy of numerous ganglion-cells in the anterior horns. The sclerosis involved also the anterior columns and the anterior portion of the lateral columns. A similar process was present in the lower part of the cervical region. The blood vessels passing in the septa from the periphery of the cord into the posterior columns were filled with blood and surrounded by granule cells and fatty detritus. In the diseased areas were present numerous small vessels surrounded by one or more layers of round cells. The changes corresponded in general with those found in acute myelitis, as well as passive swelling in consequence of edema. The presence of old diffuse sclerosis is accepted as evidence that the acute lesions represented the beginning of the sclerotic process. The sequence of events is believed to have been a perivascular inflammation, resulting in injury to the adjacent nervous structures, and inducing, especially, a disintegnation of the medullary sheaths, the axis-cylinders in general persisting. Secondarily there resulted a reactive interstitial hyperplasia.

Pulsating Vessels in the Pharynx.—This unusual anomaly was observed by McBride (*Edin. Med. Jour.*, December, 1896,) in three cases. In the first of these a large arterial trunk could be felt in the right posterior pillar of the fauces. There was a systolic but no diastolic aortic murmur. The second case was that of a man who presented a fluctuating and pulsating tumor in the region of one tonsil. It was thought that it might possibly be aneurismal, but upon operation it was found to be a cyst. In the third case the pulsation was evidently due to an anatomical abnormality. In this case there was also a systolic aortic murmur, and the carotid, subclavian, axillary, and brachial arteries showed marked pulsation.

The occurrence of pulsation in the pharynx is of considerable clinical importance. No one would be likely to plunge a sharp instrument into a pulsating tumor in this region without most careful examination and consideration, but the existence of arterial abnormalities such as those spoken of should be recognized by all practitioners who may be called upon to treat an acute throat affection.

Pulmonary Insufflation.—Operations upon the thoracic organs could be easily performed if it were possible to open the pleural cavity without disturbing the physiologic construction of the lung. Tuffier and Hallon (*Gaz. Hebdom. de Méd. et de Chir.*, November 26, 1896,) have accomplished this object by insufflation in numerous operations upon dogs. After a dog is chloroformed, a long copper tube is passed through the mouth into the larynx and connected with a bellows. Artificial respiration being thus established it is possible to open the pleural cavity, explore it by means of an electric light, and perform various operations upon the esophagus, the sympathetic and pneumogastric nerves, etc. This artificial respiration has no injurious effect upon the pulmonary circulation, and the dogs thus operated upon recovered perfectly.

THERAPEUTIC NOTES.

An Epidemic of Soor and its Treatment.—Grosz describes an epidemic of soor which occurred in the Maternity Hospital at Budapesth. Within two years 233 of the 715 infants born were affected with soor. The most carefully carried out prophylactic and hygienic measures, such as cleansing of the rooms and their disinfection by means of sulphur and thorough airing; the care of the children by special nurses, and frequent washing of the nipples, had only a temporary effect on the outbreaks of the disease. It was only after the daily brushing of the mouths of all new-born children with a one per cent. solution of nitrate of silver that the epidemic was brought under control. The few cases which then developed were of a milder character, and recovered after they had been swabbed daily with a 2–3 per cent. solution of nitrate of silver. No unpleasant effects of the treatment were observed. (*Jahrb. f. Kinderheilk*, Bd. 42, 2.)

The Care of Premature Infants.—Schmidt describes his treatment of an infant born seventy days before full term, weighing at birth 1,490 grammes and at the end of the first year 7,000 grammes. At that time it was in perfect health and had already six teeth. The success of his treatment rested upon the two points of careful maintenance of warmth and feeding with the milk of its mother. The heat of the child was preserved not only by warm flannel clothing, hot bottles and a position of the basket near a warm stove, but by the avoidance of all unnecessary cooling, *e. g.*, in washing, in the changes of the temperature of the room, etc. Until the child was old enough to nurse, the milk was drawn from the breast by an ordinary glass pump. (*Jahrb. f. Kinderheilk*, Bd. 43, 3 u. 4.)

The Treatment of Warty Growths of the Genitals.—W. S. Gottheil, in a paper on Epithelioma of the Penis, read before the Society for Medical Progress, November 14, 1896, concludes as follows:

1. Warty growths of the genitals, more especially in the male, are always to be suspected of malignancy, no matter how innocent they seem.
2. They should either be left entirely alone or be thoroughly removed by knife or cautery.
3. Imperfect attempts at destruction by nitrate of silver, carbolic acid, etc., are especially to be avoided, as in many recorded cases they have apparently stimulated a benign growth into malignant action.—*International Journal of Surgery*, January, 1897.

In the Treatment of Lobar and Lobular Pneumonia Véret (*Archives de Médicine et de Pharmacie Militaires*, September, 1896, p. 158) recommends the inhalation for ten minutes six times in the twenty-four hours of the following formula in spray:

Creosote	½ ounce
Phenic acid } aa . . . Alcohol }	80 minims
Glycerin	1½ ounces
Alcohol, 95 per cent. . .	6½ ounces

When the solution is to be employed it should be diluted with an equal quantity of distilled or filtered water. It is important that all of the constituents should be of the utmost purity.

THE MEDICAL NEWS.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

COMMUNICATIONS are invited from all parts of the world. Original articles contributed *exclusively* to THE MEDICAL NEWS will after publication be liberally paid for (accounts being rendered quarterly), or 250 reprints will be furnished in place of other remuneration. When necessary to elucidate the text, illustrations will be engraved from drawings or photographs furnished by the author. Manuscripts should be typewritten.

SATURDAY, FEBRUARY 20, 1897.

THE SCOPE AND PURPOSES OF THE RECENT ACTION OF THE NEW YORK BOARD OF HEALTH.

To anyone who reads carefully and thoughtfully the recent announcement of the New York City Board of Health, printed in the MEDICAL NEWS of January 23d, in which the necessity for municipal supervision of tuberculosis is set forth, it would seem that no further argument was necessary in order to gain cordial approval of its action. If the history of the movement of the Board looking to the more intimate supervision of this disease is reviewed, the fact becomes apparent that in making its regulations a part of the sanitary code, the Health Department was simply legalizing measures that had already been in operation under successive resolutions of the Board extending over a period of several years. To thoroughly understand the situation, it is important to review briefly the progress of this movement.

The first official action by the Health Department regarding pulmonary tuberculosis was taken in 1889, when a resolution was passed calling upon the consulting pathologists of the Department for a report on the methods to be adopted for the prevention of the disease. A communication on this subject was prepared by T. Mitchell Prudden, Henry P. Loomis, and Hermann M. Biggs, and presented to the Board. In this special emphasis was laid upon the following facts:

1. That tuberculosis is a distinctly preventable disease.
2. That it is not directly inherited, and
3. That it is acquired by direct transmission of the tubercle bacillus from the sick to the healthy, usually by means of the dried and pulverized sputum floating as dust in the air.

The measures then suggested for the prevention of the spread of tuberculosis were (1) the security of the public against tuberculous meat and milk, attained by a system of rigid official inspection of cattle; (2) the dissemination among the people of the knowledge that every tuberculous person may be a source of actual danger to his associates, if the discharges from the lungs are not immediately destroyed, or rendered harmless; and (3) the careful disinfection of rooms, and hospital wards, that are occupied, or have been occupied, by phthisical patients.

It was determined first to follow the second suggestion only, namely, the dissemination of knowledge among the people regarding the nature of tuberculosis. Circulars were therefore prepared and widely distributed, and certain measures were taken in regard to the recording of houses in which tuberculous patients had died. No further action was taken by the Health Department until 1893, when a communication was received from the Pathologist and Director of the Bacteriological Laboratory, which contained statements and recommendations that were adopted on February 13, 1894, and were, under resolution of the Board, put into force.

These declared positively that tuberculosis is a communicable disease, that all cases presented at hospitals or dispensaries must be reported to the Board of Health, and that rooms in which patients have died of tuberculosis must be disinfected to the satisfaction of the Board before they can be again occupied. A notice was also printed and affixed to the entrance doors of infected apartments in tenement houses, declaring the premises infected and forbidding the rooms to be occupied until disinfected. Nothing could be better calculated to impress the ignorant denizens of the tenement houses with the fact that tuberculosis is a communicable disease than these official placards. These people were already accustomed to similar notices in connection with smallpox, typhus fever, diphtheria, etc., and the signature of the Board of Health carried with it a feeling of terror.

The Board, since that time, has been carrying on this work, acting under the resolutions of that date. More than 4000 cases of tuberculosis were reported during the first year; something over 5000 during the second year, and nearly 8500 during the third year. The premises where these cases occurred, and also the premises where deaths from tuberculosis occurred—numbering nearly 6000 each year—have, so far as has been possible with the force of inspectors at command, been inspected, the families and the individuals have been instructed, and, where premises which have been occupied by consumptives have been vacated by death or removal, they have been placarded to prevent reoccupation, when it was considered necessary, and orders have been issued for their renovation. Very great progress has been made in this matter during these years, and in certain of the tenement-house districts of the city information in regard to the nature of pulmonary tuberculosis, and the methods of its extension, and the means to be taken for its prevention, have been widely disseminated. It is reported by inspectors that among the more intelligent of the tenement-house population more or less efficient precautions are being now observed. Moreover, the statistics of the Health Department in regard to pulmonary tuberculosis show that there has been a steady and continuous fall in the death rate for a series of years, altogether amounting to more than thirty per cent., and it is the firm conviction of the Board that by the intelligent enforcement of proper measures this disease may be, within a few years, restricted to far narrower limits, and that the enforcement of these measures will in nowise work a serious hardship to the sufferers from it. Great obstacles have been met with in the prosecution of this work, owing to the lack of facilities for the care of cases of pulmonary tuberculosis, which are of such a nature as to be dangerous sources of infection to other persons; and also owing to the fact that, as the action of the department was under resolution, and not a provision of the Sanitary Code, the recommendations and requirements could not be legally enforced. Many cases were being constantly reported by the inspectors where persons in the poorest circumstances, or under the most unfavorable hygienic conditions, suffering with advanced pulmonary tuberculosis, persistently ignored or neglected the simple and obviously necessary precautions for the prevention of the spread of the disease. Large numbers of other persons were frequently being exposed to most dangerous infection in workshops and in the crowded tenement-house districts, and the department was helpless to interfere. To enable the Board to enforce these salutary regulations, they were incorporated as a part of the Sanitary Code on January 11, 1897, as follows:

"Section 225. That pulmonary tuberculosis is hereby declared to be an infectious and communicable disease, dangerous to the public health. It shall be the duty of every physician in this city to report to the Sanitary Bureau, in writing, the name, age, sex, occupation, and address of every person having such disease who has been attended by, or who has come under the observation of such physician for the first time, within one week of such time. It shall also be the duty of the commissioners or managers, or the principal, superintendent, or physician of each and every public or private institution or dispensary in this city to report to the Sanitary Bureau in writing, or to cause such report to be made by some proper and competent person, the name, age, sex, occupation, and last address of every person afflicted with this disease who is in their care or who has come under their observations within one week of such time. It shall be the duty of every person sick with this disease, and of every person in attendance upon anyone sick with this disease, and of the authorities of private institutions or dispensaries, to observe and enforce all the sanitary rules and regulations of the Board of Health for preventing the spread of pulmonary tuberculosis."

It has evidently not been the policy of the Health Department in the past, nor, we infer, is it its purpose in the future, to inspect or interfere in any way with those cases of pulmonary tuberculosis which are under the regular supervision of a medical attendant, especially those dwelling in private houses, which are not active sources of danger to others. It has been stated that the *sole source* of *danger* in pulmonary tuberculosis is the *sputum*, and that if this be properly destroyed, a consumptive may be free of danger to his most intimate associates.

The importance of a special hospital for the care of cases sufficiently advanced to become sources of infection is presented by the Board in its announcement, as:

The importance of provision for the separate care of persons suffering from other forms of communicable disease has long been universally admitted, and the maintenance of separate hospitals for these diseases is justly recognized as one of the most effective of the sanitary measures for securing public safety. There are most urgent reasons why similar measures should be adopted in dealing with pulmonary tuberculosis.

A large experience in this matter has shown that in institutions devoted solely to the care of consumptives, the general welfare of the patients is more easily fostered, the risk of fresh infections more certainly diminished, and the chances for recovery more surely enhanced than in general hospitals in which all classes of cases are received.

We believe that such an institution in charge of the Health Department would secure all these advantages, without encroaching in any way upon the province of the institutions *now caring for such patients*, and would contribute, as no other measure can do, to the success of the endeavor of the Department, now pursued in the face of hopeless obstacles, to curtail the ravages of pulmonary tuberculosis in New York.

This is the feature of the announcement that has met with criticism on the plea that it is not the function of sanitary authorities to treat disease, and therefore no hospital is necessary. It is submitted in all candor that the treatment of the disease is not the object aimed at in this recommendation, but a place in which the extremely infectious cases can be isolated from the healthy members of the community and have proper surroundings and care. To accomplish this in some instances, and these the most urgent, it is necessary to be armed with the authority of the law, and in order to keep patients under restraint the Health Board must have a hospital under its own control. The Commissioners of Charity have no authority to restrain a patient or compel him to remain in a hospital against his will.

THE DISPENSARY AS A FINANCIAL INSTITUTION.

THE real objection raised to the present method of conducting dispensaries is based upon the fact that from the objector's standpoint they do too much business and he too little. The natural wish is, therefore, to reduce the amount of the business done by the dispensaries in order to increase that done by the doctors. A very little thought will convince any one that it is hopeless to persuade the dispensary physician to change the present system. The number of men who will be willing to spoil their own dispensary classes for the rather uncertain possibility of benefiting some other physician must ever remain small; and attempts of this sort if engaged in by a few dispensaries will result principally in building up the attendance at the other dispensaries.

To be absolutely candid, running a dispensary is a business, and not so bad a business either. Ten cents from every patient will almost pay the running expenses of a large dispensary if only simple appliances and inexpensive drugs are used. Add to this the allowance granted by the city, and the deficit remaining to be made good by private contribution is not great.

Now if it is really desired by the medical profession of New York City to cut down the number of dispensary patients the way to do it is to cut off the revenue of the dispensaries. This might be done in two ways: the mildest measure would be to withhold city aid from any dispensary which accepted from the patient a fee for treatment, for medicine, or for dressing. A more radical measure would be to make it illegal for any dispensary to accept any money from a patient. Either of these plans is practical and could be carried out without difficulty. The result would be that some of the dispensaries would be obliged to close altogether, while others would have to curtail expenses and treat fewer patients. The effect upon the patients who did attend would be that they would recognize in the dispensary a *charitable* institution. At present most of the patients who pay ten cents think that they have settled their full obligation. It is no uncommon experience to hear some woman at a dispensary confess with mortification that she has no money and will have to accept charity, when for weeks she had been coming joyfully with her ten cents, holding her head erect as befitting one who pays her just debts.

This is not an argument either for or against dispensary practice, but simply a suggestion regarding ways and means. These institutions occupy after all somewhat the same relation to the physicians of the city as the department stores do to the small shop keepers. If it is the determined wish of a majority of the profession materially to reduce the amount of business done by the dispensaries an efficient and thoroughly business-like way, to accomplish it is by putting in force some such financial measure or measures as those suggested above.

RECENT PROGRESS IN DERMATOLOGY; SOME PARASITIC DISEASES.

IT is a good thing for our peace of mind that we are provided with limited vision so that we cannot see all the forms of life that exist about us and on us, ready at all times to invade our bodies. J. F. Payne of London, in a recent address (*Brit. Jour. Dermat.*, 1896, viii, 267) applies the apt term "Bacterial nurseries" to those regions of the body that are prone to harbor parasites, such as the skin between the toes and under the nails, the scurf of the scalp, the perineum, scrotum, and adjacent parts. In all these locations the skin is more or less constantly warm and moist and well fitted to give lodgment to microörganisms which are harmless until the proper conditions arise to render them actively virulent. Impetigo contagiosa derives its highly contagious character, according to Payne, from a gradually evolved virulence. A healthy young person, for instance, may have a wound on his foot. Influenced by the saprophytic cocci of the part this sooner or later suppurates. Cocci cultivated in this local inflammation become sufficiently virulent to produce vesicles and pustules in the neighborhood; these, transferred by the nails to the face, develop classical impetigo contagiosa lesions. Transference from one case to another in rapid succession heightens the virulence of the organisms and produces the specific disease.

Eczema is not regarded by Payne as a parasitic disease. Its bilateral symmetry, its manner of spreading, often appearing suddenly in widely separated parts, the marked influence on it of nervous disturbances and digestive disorders, and the absence or rarity of instances of contagion separate it sharply from the class of parasitic diseases, such as ringworm. But without doubt certain clinical features may be impressed upon it by saprophytic organisms which, in consequence of some preliminary disturbance of nutrition, acquire pathogenic properties. Like impetigo contagiosa, eczema is prone to start from the scalp, feet, and genitals, and it is probable that all eczemas are locally infective. It is rare that the microbes found in eczema—and several of them have been found—acquire virulence enough to become contagious to others.

It is only in the past few years that we have been wakened from our dream that ringworm was caused by one parasite, the trichophyton. But now each year seems to bring to our knowledge new varieties of microörganisms giving rise to the clinical picture of ringworm. Fox and Bloxall (*Brit. Med. Jour.*, 1896, viii, 241, *et seq.*) have been investigating the subject along the road blazed out by Sabouraud. They find that his microsporon is readily recognized, and causes about eighty to ninety per cent. of all the ringworm cases in London. They have found it not only in scalp cases, but also in cases on the glabrous skin of the face, neck, and shoulders. This form of fungus affects children chiefly.

Krosing (*Archiv. f. Derm. u. Syph.*, 1896, xxxv, 184) on the other hand, after an exhaustive study, says that Sabouraud's division of the trichophyton into large and small spored varieties is not justified, as the spore formation varies in the same fungus and in the same culture. With this also falls the division of the human trichophyton according to location. Both deep and superficial inflammations are caused by the same fungus, and we therefore cannot diagnose the clinical forms from examination of the fungi. Waelsch (*Archiv. f. Derm. u. Syph.*, 1896, xxxv, 23) declares that the trichophyton grows not only in the hair but also in the corneous cells of the hair follicle, and by its growth sets up inflammation, a folliculitis and perifolliculitis. The amount of inflammation depends upon the anatomical structure of the part, being most intense in the beard where the subcutaneous tissues are loose, and the blood supply abundant. The tightness of the subcutaneous tissues of the scalp makes it a poor ground for deep inflammation. Pus cocci take no part in the inflammation set up by the trichophyton. Like Krosing, he holds that it is not possible to differentiate specific forms of ringworm as due to specific forms of fungus. In this view he is supported by M. Pelagatti (*Monatshft. f. prkt. Derm.*, 1896, xxiii, 515) who says that it is impossible to tell from the clinical appearances of a lesion to which fungus it is due, as every variety of fungus can produce the same clinical form.

While it is somewhat discouraging to find such varying opinions emanating from such skilled observers, it is evident that there is more than one form of fungus causing ringworm.

We have been familiar for a great many years with the microsporon furfur as the cause of chromophytosis, or tinea, or pityriasis versicolor, but nevertheless it has been found impossible to obtain a pure culture of it. This has at last been done by T. Spietschka (*Archiv. f. Derm. u. Syph.*). Not only has he made a pure culture of it, but he has reproduced it by inoculation in one case, and from the fungus in this case made a pure culture.

George Thomas Jackson, M.D.

ECHOES AND NEWS.

A Cure for Rinderpest in Cattle.—Dr. Koch announces from South Africa that he has found an antidote or prophylactic for rinderpest in cattle. It consists of the injection of serum into the veins, which gives immunity within a fortnight.

German Drugs.—The *German Journal of Pharmacy* estimates that 117 new remedies were introduced on the market during the four months of May, June, July, and August, 1896. It is very evident that serum-therapy has not entirely monopolized the field yet.

Surgeon-Dentists Exempt from Jury Duty.—A bill has been introduced in the New York Legislature extending to all surgeon-dentists the same exemption from service as trial jurors that is now accorded to physicians, pharmacists, and veterinarians throughout the State.

The Medical Profession in France.—It is proposed in some of the French medical journals to establish among the doctors of France a professional Court of Honor. The functions of this order will be to purge the profession of disreputable members, to suppress disreputable practices, and in general to take the part of a keeper of the professional conscience.

The Bacillus of the Bubonic Plague Easily Destroyed.—Dr. Roux, head of the Pasteur Institute, Paris, gives the encouraging news that the bacillus of the bubonic plague has little power of resistance, and that all antiseptics kill it. It dies at a temperature of 140°F., but it retains vitality in the soil, which is an explanation of the fact that it is never eradicated from Eastern countries.

Anti-diphtheritic Serum in Solid Form.—The latest announcement of Behring is that he will in future supply serum in solid form. The advantages are that no antiseptic will be necessary to preserve it. Thus modified it will not undergo any change for an indefinite time, and the accidents which sometimes resulted from its use, and which were attributed to the antiseptics, will be avoided.

Precautions Against the Plague.—The Russian government has forbidden pilgrimages of Moslems to Mecca through Russian territory, and has also forbidden Russian Christians to visit the shrines in the East. These measures are taken as a precaution against the bubonic plague, and cordons of officers have been assigned to closely watch the Russian frontiers to prevent the introduction of the plague.

Professor Nocard of Paris an Authority on Tuberculosis.—The Faculty of Medicine of Paris has conferred the Lacaze prize amounting to $2000 upon Professor Nocard for his recent work upon tuberculosis. His original contributions to this subject consisted in discovering, in connection with Roux, that the tubercle bacillus could be cultivated in a glycerin medium so that its properties could be studied and tuberculin obtained in large quantities.

The Decadence of the Cigarette.—An anti-cigarette bill has passed the Lower House of the Tennessee Legislature by a unanimous vote. It prohibits absolutely the sale of cigarettes and of cigarette papers in the State. The law goes into effect May 1, 1897. A wide movement is on foot in the public schools of the country whose aim is not only to enlighten the children regarding the injurious effects of cigarettes but also to secure signatures to a written pledge of abstinence from their use.

New York Academy of Medicine.—At the meeting of the Academy held February 4th, the retiring President, Dr. Joseph D. Bryant, made some valedictory remarks, and the President-elect, Dr. Edward G. Janeway, was inaugurated. In his address Dr. Janeway suggested the desirability of establishing a pathological laboratory at the Academy for the service and convenience of the members, and recommended that a committee be appointed to consider the vexed question of medical experts in criminal trials and bring the subject before the Academy for general discussion.

The New York Hospital for Ruptured and Crippled.—We learn from the thirty-third annual report of this institution that 10,592 new patients were recorded for treatment during the year ending September 30, 1896. It is also stated that the extraordinary demands made upon the Hernia Department since the operation of laparotomy has become so popular makes it very difficult to supply with abdominal belts and supporters of all kinds the large number of patients requiring them. It is noticeable that a large proportion of the imperfect abdominal walls resulted from operations for appendicitis.

Fortunes of British Physicians.—*The Practitioner* records the following amounts devised by doctors in England who have died during the year 1896: Dr. Patrick Fraser, $2,100,000.00; Sir John Erichsen, $450,000.00; Sir George Humphry, $400,000.00; Dr. Samuel Holdsworth, $265,000.00; Dr. William Statten, $200,000.00; Dr. George Harley and Sir William Moore each $125,000.00; Sir George Johnson and Sir Russell Reynolds each about $60,000.00. The comment is made by the same authority that these fortunes were not made so much by the accumulation of fees as by judicious investments.

The Weber-Parkes Prize and Medal.—We learn from the *British Medical Journal* that in 1894, Dr. Hermann Weber presented to the Royal College of Physicians of London, the sum of £3000 to found a prize for the best essay on some subject connected with the etiology, prevention, pathology, cure or treatment of tuberculosis, in memory of the late E. A. Parkes, M.D. The prize is to be awarded triennially, and the value will be about £150 ($750). A bronze metal will accompany the prize, and a second medal will be awarded to the second best essay. The competition is open to the medical profession of all countries. The first award will be made this year.

Death of Dr. Bourgoin.—Dr. Edwin Bourgoin, the famous French chemist, died in Paris February 11, 1897. He was one of the most distinguished of French physicians. For some time he ardently opposed the theories introduced by Pasteur. He was born in 1836. His medical education was received under the Faculty of Medicine and Pharmacy at Paris, and in 1879 he was named as Professor of Pharmacy in the latter institution. He was elected a member of the Academy of Medicine the same year. In 1867 he was chosen as head of the Children's Hospital, and in 1881 as a member of the Public Council of Hygiene. He was decorated with the ribbon of the Legion of Honor in 1880, and was made an officer of the Legion in 1891.

Government and State Aid Asked for.—A report adopted at the second Pan-American Congress, held last November at Mexico City, has been presented to the United States Senate regarding a Department of Public Health for the United States. The bill proposes gathering information from every possible source relating to public health, sanitation, food, and diseases. It asks the appointment by the President of a statistic and compiling secretary, at a salary of $8000, with an assistant at $5000. The information thus gathered is to be published for issuance each week. The committee in addition recommends the passage of uniform laws, National and State, regulating the importation, exportation, sale, and inspection of food, laws regarding the sale of drugs and chemicals, sanitation of railroad cars, hospitals, and jails, and an appropriation of money by the States and General Government for the scientific investigation of public health matters in this and foreign countries.

The Annoyances of European Quarantine.—A traveler who arrived at Trieste on an Austrian Lloyd steamer a few weeks ago has involuntarily acquired a large amount of the sort of fame which results from the baffling of public curiosity. He was from Bombay, and the Italian authorities were intensely alarmed lest he had brought the bubonic plague along with him. At first they refused to let him land at all, but finally permitted him to do so, on condition that he submit to a dreadfully thorough course of disinfection and would promise to continue his journey in a private car into which he and his baggage should be carefully sealed. To this he consented, and in his prison on wheels, which was placed between the engine and the baggage car, he started for the north. At Undine, the formalities of inspection and fumigation were again carried out. At Verona the process was repeated, and then Milan's officials tried their hands at the work before sending him on toward the Swiss frontier. There they were still more cautious, for they refused to let him enter the republic on any terms whatever. So back to Milan he was taken, still in the sealed car. Here the farce ended, for after a fifth examination and disinfection the man was released and permitted to go where and as he chose.

CORRESPONDENCE.

"A REVOLT AGAINST THE LODGE."

To the Editor of THE MEDICAL NEWS.

DEAR SIR: The editorial published in THE MEDICAL NEWS for January 2, 1896, relative to "A Revolt Against the Lodge" was read with much interest, and a hearty response is made to your plea, for we are so unfortunate as to have a doctor (?) here who recently, upon the instituting of a new beneficial lodge, offered to examine the first twenty-five free of cost. It is needless to add that the offer was accepted, and that he is now the official examiner.

What chance have we, who are anxious to better our condition, when such a freebooter is in our midst? He is beyond the pale of censure, for he was expelled from our County Society some six years ago for inciting a malpractice suit.

This is merely a line of congratulation; I write you that you may know of a new evil in the contract field of lodge work. Yours truly,

J. O. HOWELLS, M.D.

BRIDGEPORT, OHIO,
January 6, 1897.

OUR PHILADELPHIA LETTER.

[From our Special Correspondent.]

MEETING OF THE PHILADELPHIA PEDIATRIC SOCIETY—UNILATERAL TUMOR IN CHILDREN—RECOVERY FROM CERVICAL PACHYMENINGITIS—PASTEURIZATION OF MILK—NOMA—ENURESIS—MEETING OF THE PHILADELPHIA COUNTY MEDICAL SOCIETY—THE HOSPITALS, THE DOCTORS, AND THE COMMUNITY—DR. J. P. MANN APPOINTED PROFESSOR OF CLINICAL ORTHOPEDICS IN THE MEDICO-CHIRURGICAL COLLEGE.

FEBRUARY 13, 1897.

AT a stated meeting of the Philadelphia Pediatric Society, held February 9th, Dr. J. P. Crozer Griffith presented two cases of unilateral tremor in children. In neither instance could a satisfactory explanation be given of the etiology of the condition. In the first patient shown, a lad of about ten years of age, the tremor, presumably post hemiplegic, could be demonstrated as being always present in the left hand and arm, but could not be shown in the foot and leg of the same side except on attempted motion, when, as in the arm, it was plainly evident as a coarse ataxic movement. The tremor in the second case involved the left arm and leg, and side of the neck, was always present, and was made coarser and more striking on attempting volitional movement.

A case of recovery from cervical pachymeningitis was shown by Dr. Alfred Hand, jr. This case in its inception several years ago had been variously diagnosticated as hysterical paraplegia, amyelotrophic lateral sclerosis, etc., but its course and development, with the added symptom of pain, finally confirmed the diagnosis first given.

Dr. J. P. Crozer Griffith in a paper on Pasteurization of milk, explained the theory and practical workings of the Freeman Pasteurizer. An outer receptacle of tin contains a measured quantity of water which is brought to the boiling point. In this are placed eight or ten zinc cylinders containing bottles, holding the milk to be Pasteurized, which stand in water the temperature of the room. The whole apparatus is covered and set away out of a draft on a non-radiating substance. In about fifteen minutes the boiling water has conveyed enough heat to the milk to raise it to 155 ° F., the best heat for this process, and it is maintained at that temperature for the remaining time. The bottles are now taken out and cooled under running water, then put away on ice to be used as desired. Pasteurization by this apparatus Dr. Griffith considered the best means of rendering milk free from bacterial infection, but when this or similar appliances could not be had, he believed sterilization to be the better process, for, in unskilled hands the regulation of the temperature could not be relied upon.

A case of noma was reported by Dr. C. H. Weber. The points of interest in the case were (1) the inability to establish any causal factor for the lesion; (2) the remarkable vitality of the patient, which was fully sustained until the growth had assumed such proportions as to mechanically interfere with the taking of nourishment; (3) the remarkable rapidity of the growth and its intractability to treatment; (4) the fact that, although involving almost one-half of the area of the face, the median line had not been traversed.

In a paper on enuresis, Dr. J. H. McKee, after reviewing the physiology of the act of micturition, divided the causes of this condition into (1) malformations of any part of the genito-urinary tract that would interfere with the proper functionating of this system; (2) developmental or acquired disease of the central nervous system which would tend to disturb the normal equilibrium of the centers of control; (3) functional disturbance arising from such conditions as rickets, tuberculosis, or valvular heart disease; (4) nutritive disorders, such as disease of the gastro-intestinal tract; (5) faulty metabolism from any cause.

The practice of removing the prepuce with the idea that nocturnal incontinence of urine could be remedied in all cases by this means, Dr. McKee considered unwise in the extreme. For the treatment of this condition the remedy of the underlying cause should be effected, and the proper tone given to the spinal centers by alternating hot and cold douches to the spine, strychnin in tonic doses, and electricity, if required. As a simple remedy, but one that had proved remarkably successful in his hands, Dr. J. F. Prendergast mentioned cold douches to the spine just before retiring. In a series of almost 100 cases of nocturnal incontinence of urine treated by this method alone, full control of the bladder had been established within a very short time after the commencement of the treatment.

At a meeting of the Philadelphia County Medical Society held on February 10th, Dr. Edward Jackson read a paper on "The Hospitals, the Doctor, and the Community," which evoked considerable discussion without a conclusion being arrived at that would satisfactorily adjust the relationship between these three components of our civilization. This question as to how medical charity can be bestowed so that only the deserving shall be benefited and at the same time the interests and welfare of the medical profession shall be best protected, is one of vital importance, especially to the young and struggling practitioner.

That many a patient is treated free of charge, especially in the dispensaries, who is well able to pay for medical attendance, is a matter almost too well known to repeat. That positions in dispensary or hospital practice are never allowed to go begging by the medical profession is another well known fact. Strange though it is that these two conditions should exist at the same time, it would appear as though the latter is the outcome of the young practitioners having to accept the first postulate as the inevitable, with the full knowledge that though his pocket may suffer for the present, the experience gained by so doing may, and in the majority of cases will, offset this loss in the future. A remedy that might prove effectual in the dispensary evil, at least of sufficient merit to warrant a trial, was suggested by Dr. John B. Roberts. The applicants for attendance are treated once, and then told that the treatment will not be continued unless they can return with a form filled out by two reputable citizens to the effect that they are deserving of the charity they seek.

At a meeting of the Board of Trustees of the Medico-Chirurgical College held on February 8th, Dr. James P. Mann was unanimously elected clinical professor of orthopedics in that institution. For a term of years Dr. Mann has been connected with the Jefferson Medical College as chief of the out-patient orthopedic department and instructor in orthopedic surgery.

OUR PARIS LETTER.

[From our Special Correspondent.]

RANVIER'S LECTURES ON CICATRIZATION OF WOUNDS—THE DREAD OF BEING BURIED ALIVE—URATIC AND PHOSPHATIC BONE DEPOSITS DEMONSTRATED BY THE ROENTGEN RAY—ANALYSIS OF FRENCHMEN OF GENIUS FROM LOMBROSO'S STANDPOINT—THE X-RAY NOT BACTERICIDAL.

PARIS, January 26, 1897.

Professor Ranvier at the College de France is just finishing a course of lectures explanatory of his recent work on cicatrization that has been extremely interesting. In a note to the Academy of Sciences in 1891, he published the result of his observations on the repair of wounds of the peritoneum and gave his beautifully simple description of what he considered, at the conclusion of his experiments, to be the real explanation of the healing of tissues by first intention—not an organization of the exudate that had been poured out; not a budding of the connective tissue elements of the part (for that would not occur for three or four days, and healing by first intention takes place in twenty-four to forty-eight hours), but a real healing by primary adhesion. He believes that the connective tissue cells in the edges of the wound send out prolongations along the scaffolding of fibrin that has been formed by the more or less hemorrhagic exudate which has been poured out as a consequence of the irritation of the wounded tissues, and these prolongations meet and fuse to form the cicatrix.

He now returns to the subject with the study of non-penetrating wounds of the cornea. Here, too, there seems to be, normally, no production of new elements in the process of repair. Nature seems to make use of a simple mechanical process to obtain the elements necessary to fill the gap between the edges of the wound. Ranvier first noticed that the cornea at the edges of the wound seemed to be thinner than at other points. He then demonstrated by accurate micrometric measurements that this thinness at the edges was real and not apparent. This condition of affairs exists within a couple of hours after the wound has been made, and when the surface of the wound, if it is small in size, is already covered with a thin but complete layer of epithelial cells. The appearance is just the opposite of what would be found if there had been an irritative hypertrophy for purposes of repair. The origin of the layer of cells covering the wound was then traced to the exit through the severed edges of the irregular corpuscular bodies that exist in the cornea, an agglutinative material that exuded at the same time serving to fasten them to each other and to the wounded tissues. The mechanical pressure caused by the slight change of curvature of the cornea in the neighborhood of the wound is the prominent factor in causing the liquid and cellular exudate. The whole subject is beautifully worked out in detail and the slides that illustrate his lectures are striking examples of scientific experimental pathologic histology. The suggestion is inevitable that the process of cicatrization may be a much simpler one than it has been considered to be up to this time, and that though it is one of the subjects on which perhaps most work has been done there remain interesting discoveries yet to be made.

Once in a generation, Sir Henry Thompson says, there comes over the public a wave of awesome dread of being buried alive. This present generation in France, or at least in Paris, would seem to be in the midst of this wave just now. It is almost unusual to pick up a newspaper of any kind which does not contain a discussion of this gruesome subject from some point of view. Certain medical men have not hesitated to add to the interest of the public by allowing themselves to be interviewed on the subject and have reaped the benefit of the free advertisement that accrued. Even French medical men are but human. I should expect by this time that interest'in the subject would begin to be aroused in America, for there is an epidemiology of ideas as well as of disease and, like empire, they are prone to take a westward course. The really interesting thing that has come out in the excitement is the expression of opinion of Professor Brouardel, the Dean of the Faculty and distinguished author of a number of works on legal medicine. He said in an interview the other day that after a careful investigation into all the reported cases of 'buried alive' in medical and other literature there was only one case that seemed absolutely authentic, and but very few other cases where there seemed to be doubt.

Professor Potain showed a series of Röntgen photographs at the *séance* of the Academy of Sciences January 18th that demonstrates the diagnostic value of the X-ray in a medical way from a new standpoint. The cases were a series of gouty bone lesions and the photographs showed that ends of the affected bones were infiltrated with some substance that was much more permeable to the Röntgen ray than is ordinary bone material. A series of complementary experiments made with urates and phosphate of lime contained in boxes, showed this same characteristic difference of absorptive powers in the skiagraphs. Potain suggests that the diagnosis between chronic rheumatic and gouty lesions, often so difficult to make with certainty, may be rendered much easier by this method.

One would be inclined to say that our French brethren have not as lively a sense of the ridiculous as one finds among the Anglo-Saxons. The calm way in which they analyze, for the benefit of the public generally, the character and writings of their living men of genius for the purpose of pointing out any stigmata of degenerescence that may be discoverable, strikes one as not exactly the sympathetic way we indulge the same class of people.

There was an article on Alphonse Daudet not long ago, written from this standpoint, and though in a friendly spirit, it was too much of a vulgarization of the intimacies of private life to be in good taste. Dr. Toulouse's book on Zola, a more extended essay of the same character, has, as might be expected from the well-known character of its subject and the divided opinions held with regard to his work, attracted a great deal of attention. This was doubtless the main purpose of the writer and the written about, so the book must be pronounced a success. Zola seems to have submitted to a most detailed examination, and even to have permitted a rather lengthy series of psycho-physical, psycho-sensorial, and sensorio-physical experiments. The data thus furnished to a sympathetic scientist only serve to bring out clearly the fact that it is genius and not degenerescence that is the basis of the striking if somewhat peculiar character whose writings have attracted such world wide attention, and not always from the standpoint of *pure* literature. The same data however in the hands of the famous Lombroso, the Italian criminologist, serve to demonstrate very clearly the stigmata of psychical degenerescence that lie at the root of Zola's extreme naturalism. Lombroso's review of Toulouse's book, in recent numbers of *La Semaine Médicale*, have been rather spicy reading, although I should not imagine their perusal to be very pleasant to the subject who so ingenuously submitted himself to psychological dissection. To judge from Lombroso's conclusions, given the psychological elements that go to make up Zola's mental being, it was inevitable that his literary productions should have taken on the extreme naturalistic tendencies that they have. In the course of the review there is some discussion of Zola's mental peculiarities and his psycho-physical faculties that are too plain and bluntly outspoken to be pleasant. I do not not think that the notion would be as taking in America as it is here in

Paris, but I feel sure that a detailed account of the items that go to make up the mental balance of some of our popular writers would attract a good deal of attention. *Voila!* a field for some of our rising young physiologio-psychologists!

Notwithstanding all that has been said of the pretended bactericidal properties of the X-ray, mainly, it must be confessed, in what the French call political journals, no serious experiments have ever confirmed the pretended discoveries. On January 22, Professors Achard and Lannelongue, in a report to the *Société des Hopitaux*, announced that they had not been able to detect the slightest influence either on the rapidity of growth or the virulence of cultures of microbes exposed for long periods to the action of the ray.

Occasionally, reports appear of cutaneous irritation due to long exposure to the X-ray, sometimes of an extremely unpleasant character, though not very serious. There have even been reports of a depilatory action, so that there would seem to be either a certain personal idiosyncrasy in the matter, of which it would be necessary to take account before exposing the patient to the action of the ray for a long *séance*, or else certain receptive states of the skin or general system that may yet give a clue to therapeutic uses of the wonderful penetrative power of the actinic agent whose history has just begun.

Here seem to be two words that there might be use for in English. The hybrid compound 'tissue-therapy' is replaced by many writers by 'organo-therapy' but it is not the organs themselves that are therapeutic but their secretions, and so the word 'opotherapy' has been suggested by Grasset, *οπος*, meaning sap secretion. Some one spoke the other day of 'the misoneism of the veteran practitioner' and it seems such an improvement on our blunt 'old fogyism' or the now more than suspicious 'conservatism' that there would seem to be a long felt want to be filled by it.

TRANSACTIONS OF FOREIGN SOCIETIES.

London.

STRANGULATED HERNIA IN CHILDREN—THE INFLUENCE OF HEREDITY IN NEUROSES—A CASE OF "NON-CALCIFYING PLASTIC OSTITIS."

AT a meeting of the West London Medico-Chirurgical Society, January 8th, PAGET discussed six cases of strangulated hernia in infancy and early childhood. All were males and four of them were less than eight months old. The hernia was in every case an inguinal one, and in three of the six cases the cecum was in the sac.

KEETLEY formulated the following rules for similar cases: (1) Operate from the first with the full intention of bringing about a radical cure; (2) cut straight down on the neck of the sac and open it and the peritoneal cavity at the same time; (3) after returning the bowel, separate the sac high up from the cord, tie it there, and then sew up the hernial opening so that it will only just permit the cord to pass through. Preserve the heat of the child, and give a minimum amount of an anesthetic.

MCCANN believed that very few cases ever require operation. He has seen well-marked examples recover after suspension of the child. He objected strongly to taxis, whether under an anesthetic or not. Taxis is an important cause of gangrene of the bowel. He thought that many of these cases were due to intestinal distention, the result of improper feeding.

At a meeting of the Neurological Society, held January 14th, SAVAGE considered the subject of *heredity in neuroses.* He traced the ideas of heredity from the Darwinian to the Weismann periods, but he could not admit that there is no power of transmitting acquired capacities. He felt that misunderstanding had arisen from the idea of the direct transmission of fully developed habits, whereas all that is transmitted is a capacity or previous disposition for developing these habits. In the transmission of instincts it was shown that some are transmitted but never developed. There may be in fact potential abilities which are never evoked because no stimulus is present. It is thus with some neuroses which lie dormant until some special conditions rouse them into activity. There are also cases in which special forms of mental disorder occur only at certain ages.

The relation of heredity to the neuroses must be traced in various ways, one of the best being a study of the relation of the nervous disorders which often occur in the offspring of the insane and markedly neurotic. The lack of nerve power of various degree is shown by defect of one or the other of the mental factors which may give rise to various forms of idiocy or smaller degrees of mental weakness. Ordinary mania does not seem to have a sufficiently definite physical basis for it to be transmissible. Melancholia, on the other hand, is especially associated with general bodily ailment and is often met with in generation after generation in certain families. The individuals in some families seem to die out in mind before body, and in some there seems to be a capacity for passing on a tendency of recurring melancholia which in the end becomes chronic. Dementia in a different way is often associated with the old age of certain families.

What in some cases looks like direct heredity is after all the result of nervous instability associated with dread and expectancy. This is well seen in some cases of puerperal insanity and in the suicidal tendency recurring in certain families. Heredity is an important factor in the production of neuroses, but their transmission depends as much on the stimulus which evokes the symptoms as on the heredity, and it is this which is so important for the consideration of the physician. There is hope in changing the surrounding of the neurotic and in thus breaking morbid habit or preventing its development.

At a meeting of the Pathological Society, held January 19th, PITTS and SHATTOCK gave the details of an unusual case for which they proposed the name of "*non-calcifying plastic ostitis.*" At the age of thirty-one the patient fell and struck her right leg. Three months later the knee became stiff and painful. She grew worse and was treated in several hospitals. The leg was wasted and flexed at the knee at almost a right angle, the tibia and fibula being displaced backward. The head of the tibia was much enlarged and was movable at the epiphysis upon the shaft, without crepitus but with severe pain. Eight years after the accident amputation was performed. The patient recovered from the operation and regained fairly good health. The tibia alone of the bones of the body was diseased. Its upper half had undergone a uniform transformation into a minutely cancellar bone-like substance so devoid of earthy salts that it was as pliable as India rubber. The medular cavity was obliterated. Microscopically it consisted of trabeculæ which were surrounded by a definite layer of osteoblasts. The spaces between the trabeculæ were occupied by a highly cellular tissue with but few leucocytes.

Pitts and Shattock found it impossible to class the specimen under the heading either of osteomalacia or osteitis deformans. They considered it an osteitis occurring in the adult of a pronounced plastic character unaccompanied by a calcification. Hence the name was proposed of " non-calcifying plastic ostitis."

KANTHACK and SPENCER looked upon the specimen as a new growth, either an osteosarcoma or a " myeloma."

BUTLIN thought the specimen illustrated a stage in ostitis deformans at which the bones are plastic and the deformity takes place. He thought there was no evidence for regarding this specimen as a tumor, because secondary growths had not occurred.

Berlin.

TWO CASES OF PULSUS DIFFERENS—THE APPLICABILITY OF MUSCULAR EXERCISE IN CASES OF CARDIAC DISEASES.

At the session of the Union for Internal Medicine, held January 11th, GERHARDT reported two cases of pulsus differens occurring in his clinic. One was in an old woman who presented symptoms of mitral stenosis and insufficiency and nephritis. The pulse in the left radial artery was smaller than that in the right. It differed from the right, also, in number, beating 98 times to the minute, while that of the right side beat 110 times. The other case was also that of an old woman, with paralysis agitans and paralysis of the right leg following an apoplectic stroke. In her case the right pulse was 112 and the left 92. At autopsy the right subclavian artery was found to have a circumference of 19.5 millimeters, while the left measured only 8 millimeters.

Speaking of the value of muscular exercise in cases of cardiac disease, FRAENKEL said that mechanical treatment of heart troubles might be advisable for three reasons: (1) In order to stimulate the heart itself; for example, in cases of neurosis of the heart. (2) To favor a widening of the peripheral vessels; for instance, in arteriosclerosis. (3) In order to reduce the peripheral resistance of the arterial system which occurs, for example, in those persons who grow very stout. The plan recommended by Hirschfeld of reducing below normal the nourishment of a cardiac patient must not be taken as a general rule. In valvular disease and arterio-sclerosis its use ought to be most carefully watched.

LEYDEN called attention to the fact that the term "a weakened heart" is used with two very different meanngs. In one class of cases the heart is really weakened, that is, degenerated, as a result of anemia, etc. In such cases the muscle of the heart has no unusual work to do, but it cannot perform its normal function. In the other class of cases the heart has more work to perform than normal, (valvular disease, arterio-sclerosis) and although its muscle may be intact it fails to perform its extra labor. In the first class of cases digitalis is poorly borne, for under its influence the muscle of the heart is soon weakened still more; in the second class, however, digitalis acts quickly and satisfactorily.

Increased muscular activity in the first class of cases is in order only during convalescence. In the second class it is entirely inapplicable except in so far as it reduces rather than increases the work of the heart. Free and deep breathing is especially important for patients with cardiac disease, and to obtain this the abdominal contents should occupy the least possible space. Hence small meals and laxatives are to be recommended.

SOCIETY PROCEEDINGS.

NORTHWESTERN MEDICAL AND SURGICAL SOCIETY OF NEW YORK.

Meeting Held November 25, 1896.

DR. SENECA D. POWELL made some remarks concerning the use of the Taylor splint in the treatment of fractures of the clavicle, and showed a patient on whom the splint had been used with most satisfactory results. The young man, who had suffered a fracture of the outer third of the clavicle from a bicycle accident, had been in great pain and agony for several hours after the injury, due to the overriding of the fragments and the spasm of the muscles. He experienced complete relief immediately after the application of the splint, and within a few hours was able to go about the same as before the accident.

Dr. Powell demonstrated the use of the splint, showed the manner of its application, and contrasted its utility with that of other forms of dressing for fractured clavicle, and concluded that this was the nearest approach to the ideal dressing.

DISCUSSION.

DR. GREENE said that he thought that this was an ideal splint, and was apparently well adapted to all fractures of the clavicle. He had tried all the other methods, and intended to try this one.

DR. PAGE thought the splint represented the best idea he had ever seen incorporated for such a purpose. He, too, had tried all forms of apparatus, but the trouble with most of them was that they caused pain, and must frequently be removed. He was favorably impressed with the splint and with the demonstration that Dr. Powell had made.

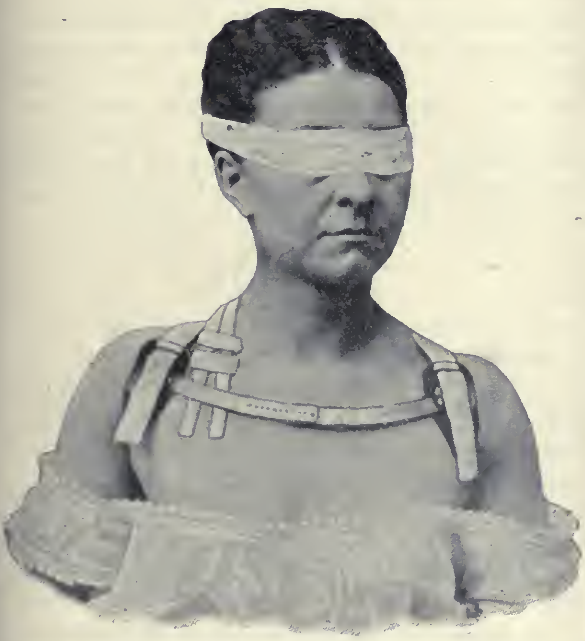
DR. DESSAU remarked that it seemed to him simple and efficacious. He thought that it might cause discomfort on account of the bar in front, but such discomfort would not be any greater than with the other methods which were usually recommended.

It seemed to Dr. Goffe that the prominent feature which recommended itself to him was that it allowed the patient free use of his arm, and thus contributed materially to its value. Heretofore, he had been satisfied with the Sayre method, but he could see the value of this over Sayre's, at least for some cases.

Dr. Bulkley was also very favorably impressed with the demonstration that Dr. Powell had made, and thought that it would be possible to make use of this apparatus for patients with stooping shoulder.

Dr. R. A. Murray thought that the splint would not meet all the indications which the ideal dressing for fracture of the clavicle should. Sayre's apparatus, to be sure, frequently allows the occurrence of a slight amount of deformity, although a measurement of a series of normal clavicles, and clavicles that had been fractured, showed that deformity was as common in the first as in the second, and such findings were in keeping with other measurements that had been made, such as on the lower extremity of a large number of individuals, in which, not infrequently, a considerable discrepancy in the length was found. He related a case in which Moore's dressing was used most effectively when others had failed. In fact, his experience had led him to favor this dressing above all others. Most dressings for fracture of the clavicle cause chafing and pain. Taylor's splint has the advantage that it does not do this.

Fig. 1.



Application of the Taylor splint for fractured clavicle. Front view.

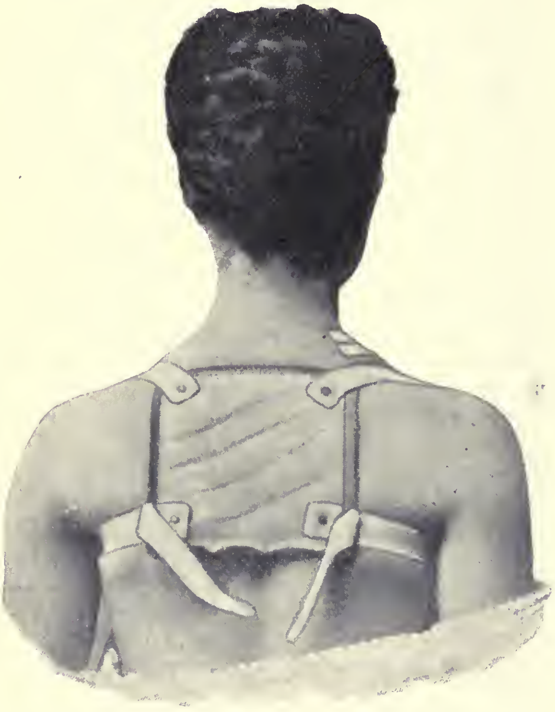
Dr. John F. Erdmann said that the excellent result in this case was due to the fact that the line of fracture was near the coracoid process. The splint had been applied to the inner side of this process, and the result was that there was no forward movement in the scapulæ. He was surprised at the amount of displacement which had taken place in this case, as he had never seen overriding of the fragments to the extent of an inch in fractures at this site. When the bone was fractured in the outer third, he thought that the figure-of-8 dressing would produce quite as good results as the application of this splint would. It did not seem to him that the Taylor splint would be applicable to fractures of the inner third of the clavicle. He related a case which he had recently seen thirty-six hours after the fracture had been produced, in which the pain was very great, but it was quickly relieved by allowing the patient to lie flat upon a hard bed to obtain the aid of gravity in reducing the deformity, and apposition of the fragments was then possible. Good results followed the use of the figure-of-8 bandage. In the case related by Dr. Powell he was a little surprised at the length of time the pain continued after the various dressings cited.

Dr. J. Blake White, after speaking of the general indications to be fulfilled in the treatment of fracture of the clavicle, agreed with Dr. Erdmann in what he had said about fractures of the inner third of the bone. In the case demonstrated by Dr. Powell, he was struck by the immediate relief that had followed the application of the splint, and the facility with which the splint had kept the shoulder in place. It was a matter of surprise that a device so useful, so easily adapted, and so perfect, had not been adopted heretofore. The entire absence of deformity in the case demonstrated showed its applicability, at least in some cases.

Dr. A. M. Phelps confessed himself pleased with the instrument and the result of its application in the case demonstrated. He remarked that it must not be forgotten that there are very different kinds of fracture of the clavicle. The attachment of the sterno-cleido-mastoid muscle and the attachment and insertion of the subclavius muscle have very much to do with the result that follows fracture of this bone. In fracture of the outer third, near the insertion of the subclavius, the fragments are easily held in place by almost any dressing. In fracture of the inner third, however, the matter is very different, and he did not see how such a splint as the one demonstrated could act upon that favorably. In these latter fractures the shoulder must be raised, and this instrument apparently did not do that. In fracture of the outer third of the clavicle, he thought it was ideal. To his mind, both Moore's and Sayre's dressings were radically wrong, when used without the axillary fulcrum or pad, because they pulled the shoulders together. In fractures of the inner third of the clavicle, the elbows should be pulled back so as to make traction on the fragment through the pectoral muscle; then, with a pad in the axilla, the shoulder was thrown outward. The external and internal fragments of the fractured ends would be coaptated by raising the shoulder. To accomplish this, in both Moore's and Sayre's dressings, a pad should be put in the axilla, and the elbow pressed against the chest and drawn backward and fastened with adhesive plaster. This lengthens the clavicle. Then, if another strip is put under the elbow and over the opposite shoulder, the shoulder is lifted, and the requirements for the treatment of such a fracture will be met. One drawback to the use of the splint that had been exhibited was that it was not available when one lived remote from the instrument-maker, and it was in these cases that three strips of adhesive plaster and the pad in the axilla became so useful. Everyone knew that in fracture of the clavicle in women it was an esthetic necessity to get a good result, and to please them with comfortable and agreeable dressings. Adhesive plaster often caused some discomfort, and he would recommend for them the dressing demonstrated, with proper modifications for fractures of the sternal end. In using the strips of adhesive plaster, he insisted that they should not be disturbed for four weeks. If it was necessary to apply fresh ones, they should be put on over the old, as often as the fracture was not in perfect coaptation.

DR. HENRY LING TAYLOR described the evolution of the Taylor clavicle splint. The anterior portion was simply the "front piece" of the improved apparatus for Pott's disease, which was added to the original Taylor brace by its inventor, Dr. C. Fayette Taylor, about the year 1876. Soon afterward the front piece, buckled to a pad at the back, was used by Dr. Taylor as a clavicle splint in several cases, with good results; later it had been used by the speaker, and in a number of cases had worked admirably. Its features were its comfort, efficiency, and the freedom it permitted the patient, who often could use the arm, though it was advisable to wear a sling for a few days. It was different in principle from any clavicle splint with which he was familiar, and was, in effect, as Dr. Powell had said, an artificial clavicle, or rather an artificial shoulder girdle. He could corroborate what Dr. Powell had said as to the ugliness of the fracture in his son's case, the helplessness of the patient, and the rapidity and completeness of the relief afforded by the application of the splint. The splint, when first applied, seemed too long, but had to be lengthened a couple of inches as the fragments were drawn into place by its application, which threw the shoulders out and back. Whether this splint was applicable to all clavicular fractures, experience would decide.

FIG. 2.



Application of the Taylor splint for fractured clavicle. Rear view.

DR. POWELL, in conclusion, said that it was necessary for him to take exception to two or three remarks that had been made, particularly in reference to the applicability of the splint to fractures of the inner third of the clavicle. In these cases, the displacement was generally of the outer fragment, and not of the inner. It was his belief that the application of the Taylor splint prevented displacement of these fragments, as the splint brought pressure to bear on the anterior portion of the scapula, and on the anterior part of the humerus, directly over its muscular attachments. It protects the outer fragment, and brings it into line with the other part of the fractured segment. Its great advantage is, as he had already pointed out, that it relieves pain, lessens irritation, and allows the patient to get about almost immediately after its application. He was of the opinion that it is as useful for fracture of the inner third as for fracture of the outer third; in fact, fracture in any part of the clavicle.

REVIEWS.

THE PHYSICIAN'S VISITING LIST FOR 1897. Philadelphia: P. Blakiston, Son & Co.

BLAKISTON'S VISITING LIST for 1897, appears in its customary compact and useful form. Physicians using it will find it serves its purposes admirably.

THE PROFESSION OF MEDICINE: ITS STUDY AND PRACTICE; ITS DUTIES AND REWARDS. By CHARLES WEST, M.D., Fellow and Late Senior Censor of the Royal College of Physicians, etc. London: Kegan, Paul, Trench, Trübner & Co., Ltd., 1896.

AN essay of reminiscence, of counsel, and advice, from one who has trod the path which doctors travel for sixty-three years, is bound to receive a respectful hearing from the members of the profession. And even if the thoughts expressed and the hopes held forth are but those which govern most sensible and honest men, and are largely rhetorical, the fact that a Nestor speaks induces one to incline the ear and silently to hearken to the old man's words of wisdom.

Extended analysis of this little book is not required. Dr. West urges broadness of study, the culture of the arts, and a healthy physique as requisites for a physician. Contrary to our own Holmes, he sees no objection in the young doctor's acquiring reputation as a *litterateur*, or as a musician. The necessary attributes of kindness, sympathy, morality, and honesty are dwelt upon pleasantly, and the aged author sees in the consciousness of work well done ample reward for the trials and rebuffs of practice. No man can be worse, and many will be better, for having read this earnest appeal.

ORIGINAL ARTICLES.

THE PHYSIOLOGICAL ACTION AND THERAPEUTIC USES OF YEAST NUCLEINIC ACID, WITH SPECIAL REFERENCE TO ITS EMPLOYMENT IN TUBERCULOSIS.[1]

BY VICTOR C. VAUGHAN, PH.D., M.D.,
OF ANN ARBOR, MICH.;
PROFESSOR OF HYGIENE AND PHYSIOLOGICAL CHEMISTRY IN THE UNIVERSITY OF MICHIGAN, AND DIRECTOR OF THE HYGIENIC LABORATORY.

Nucleins and Nucleinic Acids.—I have elsewhere spoken of nucleins as follows: "Physiologically, nucleins may be said to form the chief chemical constituents of the living parts of cells. Speaking broadly, we may say that the nuclein is that constituent of the cell by virtue of which the histological unit grows, develops, and reproduces itself. It is the function of the nuclein of the cell to utilize the pabulum within its reach. It must be evident that those tissues most abounding in cellular elements contain relatively the largest amount of nuclein. It must also be seen that it is by virtue of their nuclein that the cells of various organs and organisms possess and manifest their individual peculiarities. We should, therefore, expect to find that the nuclein of the yeast cell is not identical with that of the bacillus tuberculosis, and that the nuclein of the spleen differs from that of the thymus gland. The number of kinds of nuclein is limited only by the variety of cells. Nuclein is the chemical basis of that part of the cell designated by the histologist as the nucleus, sometimes called chromatin on account of the readiness with which it absorbs and holds coloring agents. It is the nuclein of the bacterium which takes up and retains stains, and it is on account of the fact that the nuclein of the bacillus tuberculosis differs from that of other bacilli that we are able to distinguish the former from the latter by its tinctorial properties. Differences in reaction with staining agents so plainly seen under the microscope are only outward manifestations of less apparent and more important differences in chemical composition.[2]"

Chemically, the nucleins are complex, proteid bodies, especially characterized by the large amount of phosphorus which they contain. Nucleins can be split up by the action of dilute mineral acids into albuminous bases and nucleinic acids. The nature of the base and the acid obtained in this way will vary with the nuclein in which they originate. Yeast nuclein differs in both its basic and its acid constituents from leuco-nuclein as obtained from the thymus gland. The nucleinic acids on being further broken up by the action of dilute mineral acids yield the so-called xanthin bodies, and here again it is true that the products obtained will depend upon the kind of nucleinic acid acted upon. One nucleinic acid may yield only adenin, and for this reason it may be designated as adenylic nucleinic acid, while another may furnish xanthin abundantly, possibly to the exclusion of other bases, and this may be termed xanthylic nucleinic acid. Kossel has demonstrated some of the chemical differences between nucleinic acids from diverse sources. Yeast nucleinic acid yields, on being broken up by the action of dilute mineral acids and heat, guanin and adenin; while testicular nucleinic acid furnishes adenin, hypoxanthin, and xanthin; and thymus nucleinic acid gives adenin only. These are what might be called gross differences. It is probable that finer distinctions exist between members of the same group. I have frequently observed that different samples of yeast vary not only in the amount of nucleinic acid yielded, but that the products differ in the intensity of their germicidal action. Of course this may be due to differences in other constituents of the yeast cells, and the greater or less difficulty of obtaining the nucleinic acid in an approximately pure condition. In the first year of my work on this subject I used baker's compressed yeast, and sometimes I wholly failed to obtain a nucleinic acid with distinct germicidal properties, while at other times the result was quite satisfactory, although at no time did I secure a product equal in germicidal strength to that subsequently prepared from pure cultures of brewer's yeast. It is within the range of possibility that by an investigation of the different varieties of yeast cells and with due attention to the conditions under which the cells are grown, we may secure not only a richer yield of nucleinic acid, but an acid of greater germicidal strength.

The difference in chemical composition and in germicidal action between nucleinic acids from different kinds of cells is, in some instances at least, accompanied by differences in physiological action. Thus, while Lillienfeld[1] has found that thymus nucleinic acid coagulates the blood when injected intravenously in certain quantities, it will be shown in this paper that a much larger per cent. of yeast nucleinic acid may be injected intravenously without any such effects.

---

[1] This paper contains the material used in special lectures delivered to the students of the Department of Medicine and Surgery of Michigan University, November, 1896.

[2] The Nucleins and Nuclein Therapy; Annual Address on Medicine. Transactions of the Michigan State Medical Society, 1894.

Certain substances which are histologically and functionally nucleins do not yield any xanthin base as a decomposition product. These are called paranucleins. Some of these are antecedents of true nucleins. Thus, the yelk of the egg contains a paranuclein, which may be isolated by removing the accompanying proteids by peptic digestion. This substance does not yield a xanthin base, but during the process of incubation it develops into a true nuclein.

Generally speaking, nucleins and nucleinic acids are insoluble in dilute acids and soluble in dilute alkalies. They are insoluble in alcohol. The last mentioned fact has not, however, prevented the quite extensive employment by the profession of alcohol said to contain nuclein. It is needless to say that any beneficial effects obtained by the use of this preparation should be attributed to alcohol and not to nuclein. The terms "nuclein" and "nucleinic acid" are frequently used interchangeably. In fact, it is by no means always easy to determine whether in a given kind of cell the nucleinic acid exists free or combined with some basic substance; and it is extremely difficult to obtain the nucleinic acid in any quantity wholly free from albuminous substances, and as nucleinic acid combines with any albuminous substances present, the chemist is by no means always certain which of the terms "nuclein" or "nucleinic acid" will the more honestly fit a given product.

Pure yeast nucleinic acid contains about nine per cent. of phosphorus. While a small quantity can be prepared in a sufficiently pure state to yield this amount I have so far found the preparation of such a pure article in quantities large enough for any extensive physiological experimentation or therapeutical use impracticable. The purest nucleinic acid which has been used in the work detailed in this paper contains a fraction less than seven per cent. of phosphorus.

The Theory upon which these Studies of Nucleinic Acid have been Based.—The working hypothesis which I developed in beginning my researches on the nucleins, and which may be found in my address before the Medical Section of the first Pan-American Medical Congress,[2] may be condensed to the following propositions:

1. The phagocytic theory of Metschnikoff, in so far as it teaches that the polynuclear white blood-corpuscles are active agents in preventing or retarding the multiplication of pathogenic germs in the body, is true.

As Metschnikoff has stated, there is no claim that there are not other agents which may also combat the progress of disease.

2. The polynuclear corpuscles do not eat the bacilli, but they destroy the germ by virtue of the chemical action of some constituent or secretion.

3. The germicidal properties of blood-serum, demonstrated by the researches of Fodor, Nutall, Buchner and others, are due to a substance, or to substances, that originate in the polynuclear white blood-corpuscles.

4. The natural resistance of the body to bacterial disease will be strengthened by a physiological increase in the production of polynuclear white blood-corpuscles.

5. This increase in the polynuclear corpuscles may be induced by introducing into the animal the most distinctive constituent of these cells, which is nuclein.

The foregoing statements were formulated in 1891 and I then began my studies on nuclein from yeast and from certain animal glands. In 1892 the first experiments were made on healthy and tuberculous guinea-pigs, and in May, 1893, tuberculous patients were treated for the first time with this agent.

The Germicidal Action of Nucleinic Acid.—In May, 1893, a paper by Novy, McClintock, and the writer,[1] detailed experiments by which we demonstrated the germicidal action of testicular, thyroid, and yeast nucleins upon bacillus venenosus, staphylococcus pyogenes aureus, and albus, and bacillus anthracis. Additional details of similar experiments were given in the address read before the Medical Section of the first Pan-American Medical Congress, already referred to. The paper by McClintock and myself[2] read before the same congress, demonstrated that the germicidal properties of blood-serum are due to the presence of nuclein. In February, 1894, Kossel[3] published a paper which confirmed our results.

It is unnecessary to go into any detailed statement concerning the germicidal action of yeast nucleinic acid at this time, as any one desirous of doing so can consult the publications referred to. There is, however, one point which seems to me to be of special importance, in view of certain recent German investigations. While yeast nucleinic acid is a powerful germicide, it is not equally potent with all kinds of bacteria. Indeed, there are some germs on which this acid can scarcely be said to manifest a germicidal effect. This is true of certain putrefactive germs. This is of interest, in view of the discovery of Pfeiffer,[1] that the blood-serum of an animal, immunized against a specific bacterium, becomes decidedly more germicidal to that germ than to any other. This discovery is now being utilized in attempts to distinguish the typhoid and cholera bacilli from others which closely resemble them morphologically and tinctorially. It would seem from this that the germicidal constituent of the blood-serum can be trained to act more energetically upon a given bacillus. Pfeiffer states that the germicidal constituent of the blood-serum of his immunized animals is not a nuclein, and this makes the fact that yeast nucleinic acid manifests its germicidal properties in a selective way all the more interesting.

The Effect of Treatment with Yeast Nucleinic Acid Upon the Polynuclear White Blood-Corpuscles.—As early as 1892, my colleague, Dr. Huber, kindly made for me a large number of counts of the white corpuscles in the blood of both healthy and tuberculous guinea-pigs, with and without injections of nuclein. He has since repeatedly made like determinations on the blood of my patients. I have elsewhere[2] stated his results, as follows:

(1) "The subcutaneous injection of nuclein increases the number of white blood corpuscles; (2) this increase occurs in both healthy and tuberculous persons; (3) with like quantities of nuclein injected, the increase varies with the person; it may be slight and it may be three-fold; (4) this increase occurs principally in the polynuclear cells; (5) it is evident, as a rule, as soon as the third hour after treatment, and generally disappears by the forty-eighth hour."

The following details of one series of counts may be of interest. All the persons tested in this series were tuberculous: [See next column.]

Patient.	Total No. of white corpuscles per c.m. before treatment.	Total No. of white corpuscles per c.m. after treatment.	Total increase per c.m.	Per cent. of increase.	Intervals between treatment and count.	Strength of nuclein solution used, per cent.	Amount of solution used.	Method of administration.

Recently Hahn,[3] working under the direction of Buchner, in the Hygienic Institute of the University of Munich, and using the nuclein prepared by Parke, Davis & Co., the same as that employed in the treatment of the cases reported in this paper, has gone one step further than I have in this investigation. He has shown that nuclein not only causes a hyperleucocytosis, but that the defibrinated blood taken from the animal while in this condition of hyperleucocytosis, induced by the nuclein, has its germicidal properties increased. His experiments were made upon dogs, and are detailed as follows: "First, some blood was taken from the animal and the number of leucocytes in the arterial blood was determined. Then the animal received a hypodermic injection of some leucocytosis-producing substance. For this purpose, some albuminous body, as albumose or nuclein, the latter in the form of a yeast nuclein, supplied us by the firm of Parke, Davis & Co. A nucleinic acid from the same source has given us good service. Since large quantities of this preparation can be employed, it was easy in a short time to double the number of leucocytes. At the same time, there was generally an elevation of temperature, which, with this agent, was variable. In dogs, the elevation was seldom more than from 1° to 1½°. When the number of leucocytes had reached near the double of the normal, a second portion of blood was drawn. At first we allowed an interval of only from five to six hours, later, from twelve to fifteen hours between the injection and the withdrawal of the second portion of blood. Even when the leucocytosis had begun to fall the results were not altered. The experimental proof that the leucocytosis was caused by the injection of the nucleinic acid was clear. The blood taken in the state of hyperleucocytosis was decidedly more markedly germicidal than the normal blood of the same animal. Control experiments, made morning and evening, without injection, demonstrated that the effect of the withdrawal of blood alone on an increase in the leucocytes was but small."

Table I illustrates the results obtained:

Hahn states that in man the number of white corpuscles per c.m. must be increased to at least 13-1400 before there is any marked increase in the germicidal action. In one of my cases, not included in the table given, the number reached 45,000. This, however, was exceptional, and followed a very large injection. Moreover, it was a patient in the last stages of the disease, and with numerous cavities, as was demonstrated positively later at *post-mortem*, and Stein and Erbmann[1] have shown that in this condition there often exists a marked leucocytosis.

It must be admitted from the evidence before us that yeast nucleinic acid increases the number of polynuclear white blood-corpuscles. Hahn also found the increase to be among these elements, and that it intensifies the germicidal properties of the blood.

Is Yeast Nucleinic Acid an Antitoxin?—With our present knowledge of the infectious diseases, we may hope to find curative agents in one or the other of two classes—(1) those which increase the germicidal action of the blood, and (2) the antitoxins. Indeed, the infectious diseases may be divided into two groups, one of which includes those diseases which we may reasonably hope to cure by antitoxins, and the other those which must be reached by directly or indirectly destroying the germs. The diseases for which antitoxins have been found—diphtheria and tetanus—are the best representatives, possibly the only members, of that class. Cholera and typhoid fever may finally be placed in the same group by the discovery of their antitoxins, but, in my opinion, this is not highly probable. In fact, the researches of Pfeiffer, already referred to, render it quite certain that cholera and typhoid fever are not to be combated successfully with antitoxins. The toxin diseases have the following characteristics:

(1) Their germs live in the animal body relatively only a short time; at least they manifest their virulence for only a short period. The bacillus of diphtheria may continue in the child's throat for weeks, but only for a few days does it manifest for that child any virulent activity. (2) The germs are located superficially on a mucous membrane or under the skin. (3) The germs are confined to relatively a very small area. (4) The tissue-changes induced by the growth of the germs are relatively of but little import. Diphtheria may cause death by filling the larynx with membrane, but this is not the usual cause of death in this disease, and, if it were, tracheotomy and intubation would save life. (5) Within a few days at most, the bacteria elaborate and pour into the body fatal doses of a chemical poison; then the bacteria cease, in that person, to manufacture more of the poisons. (6) These diseases are acute intoxications. The dangers to life, both those which are functional and those which are histological, are due to the chemical poison. The antitoxin does not destroy the germ, and the germ, after it has produced poison for a few days at most, is, for that individual, harmless.

The other group of diseases possesses the following distinguishing characteristics: (1) The germs may live and continue to manifest their virulence for a long time. The bacillus tuberculosis may slowly multiply and continue its existence in the same individual for many years. (2) The germs may be located either superficially or deeply; they may be confined to a small, or may extend over a large area. (3) Their germs elaborate chemical poisons for weeks, sometimes for years. An antitoxin would be possessed of no curative action in these diseases. It might be of temporary value, but the bacteria would continue to produce the poison. To cure these diseases, we must destroy the bacteria. All attempts to utilize chemical germicides in the curative treatment of disease have been failures. Our hope lies in the possibility of increasing the normal resistance of the animal body.

---

[1] "Zur Frage der Leucocytose bei tuberculösen Processen." *Deutsches Archiv. f. klin. med.*, B. 56, S. 323.

Then there are the acute septicemias—those diseases in which the germs multiply rapidly in the blood. In these also, curative agents will most likely be found in substances which either directly or indirectly destroy the bacteria.

Is yeast nucleinic acid an antitoxin? I think that I can answer this quite positively. McClintock and I have made a long series of experiments on rabbits and guinea-pigs with the toxins of diphtheria and tetanus and yeast nucleinic acid. We have failed to find any evidence that yeast nucleinic acid possesses any antidotal value against these toxins.

The Effect of the Administration of Nucleinic Acid on the Formation and Elimination of Uric Acid.—It was formerly supposed that uric acid resulted from the retrograde metabolism of proteids in the same way as urea is produced. Uric acid was supposed to represent a condition of imperfect oxidation, the completed product of which is urea. On this theory, an excess of uric acid was supposed to indicate the administration of oxidizing agents directly or of those substances which would favor oxidation processes in the blood. It was upon the last-mentioned hypothesis that alkalies were so largely given when uric acid was formed in excess. However, Horbaczewski[1] has shown that the amount of uric acid is increased by the administration of nuclein. This fits in with certain chemical and physiological facts. As has already been stated, the xanthin bases are derivatives of nucleinic acid, and the close chemical, physiological, and pathological relation of uric acid to the xanthin bases is well known. The experiments of Horbaczewski would indicate that the administration of nuclein increases the number of polynuclear white corpuscles, and in the disintegration of these the xanthin bases and uric acid result. If this be true, uric acid becomes the measure, as it were, of cellular disintegration in the body. This theory has been combated with some vigor, mostly upon theoretical grounds, aided by a few experiments upon lower animals. However, the correctness of Horbaczewski's work has been confirmed by experiments made upon man by Weintraub[1] and others. My own observations are in accord with the teaching of Horbaczewski, and I have frequently found an excess of uric acid in the urine after giving large doses of nucleinic acid. I have also, in persons suffering from rheumatic pains accompanied by the so-called uric acid diathesis, found that these pains were greatly intensified by the administration of nucleinic acid. In at least one instance was this so markedly true that the treatment was seriously interfered with and could not be given with the usual frequency. Cases of this nature are, however, judging from my experience, rare among the tuberculous.

Uric acid is not always increased in the urine after the administration of nuclein, but in all experiments on this point, in which proper tests have been made, it has been found that some one or more of the alloxan bodies is increased in amount. Uric acid is only one of the alloxan group, and failure to recognize this fact has led some writers into error which I cannot take the space to point out at this time.

Method of Administration.—In the cases reported in this and the preceding paper, the treatment has consisted of hypodermic injections. I use the syringe of a small aspirator, holding 80 minims. The barrel of the syringe should be long and of a relatively small diameter. The greater the diameter, the more difficult it is to discharge the contents through a fine needle. For the injection of larger amounts than that mentioned above, I have had a long-barrelled syringe, holding 10 c.cm., made. I select small needles, one for each patient, and keep the needles, when not in use, in an Esmarch dish filled with a five-per cent. solution of carbolic acid, and with the name of the patient on the cover. The syringe is kept, when not in use, in a covered glass dish such as is used by bacteriologists, and known as a moist chamber. When the syringe and needle are kept in this way, no sterilization further than that due to the action of the carbolic acid on the needle is needed. The small amount of the acid adhering to the needle does no harm, and possibly may be of benefit, on account of its slight local anesthetic effect. When ready to give a treatment, some nuclein solution is poured into a clean Esmarch dish, the syringe is filled from this, and the needle is taken from its dish between the thumb and finger, touching only the base, and screwed upon the syringe. I prefer the American form of syringe, with the needle screwed on the barrel, to the German form, in which the needle is more loosely attached. The point of injection being selected, the skin is rubbed vigorously with a sponge wet with a five-per-cent. solution of carbolic acid. This rubbing should be well done, and is beneficial in two ways. In the first place, it secures cleanliness, not absolute sterilization, of the part, and, in the second place, the acid slightly anesthetizes the skin. Then, with a firm hand, the needle is introduced deep into the tissue. It is not well to pinch up a fold of the skin between the thumb and finger, as some do in the administration of morphin hypodermically, but with the thumb of the left hand on one side of the point of injection and the fingers of the same hand on the other side, press down and outward, making the skin tense at the point entered by the needle. Having introduced the needle, I inject the fluid very slowly. When the treatment is given in this manner, the pain is not nearly so great as that following the injection of an equal volume of distilled water, as I have frequently demonstrated. I generally inject in the infraclavicular areas, but the interscapular space is equally suitable. The subcutaneous injections should not be made in the arms, because there is not enough tissue, especially on the arms of many consumptives, to accommodate the fluid without painful distension. The injections may be made over the abdomen, on the buttocks, or in the thighs. In fact, they may be made on any part of the body or into any accessible area of mucous membrane. In the treatment of a case of lupus of the nose, I injected into the tissue immediately adjacent, but it was quite painful. In a case of local trouble in the upper portion of the vagina, I have injected through the mucous membrane after cleansing the point selected with a cotton swab saturated with the carbolic-acid solution.

[1] "Ueber den Einfluss des Nucleins der Nahrung auf die Harnsäurebildung," *Berliner klin. Wochenschrift*, 1895, S. 405.

The five- and ten-per-cent. solutions may be injected hypodermically, provided the reaction is not excessively acid or alkaline. When properly used, the stronger solutions cause no more pain than the weaker ones.

There is always more or less objection to hypodermic medication, especially when it must be continued for a long time. There are nervous patients who always dread the needle, and it is often inconvenient, sometimes quite impossible, for the physician to give the time to the treatment necessitated by the hypodermic method. I have fully realized these difficulties, and have given attention to the question of the absorption of nucleinic acid when administered by the mouth.

Since nuclein is separated from other albuminous substances by digesting the latter with artificial gastric juice, it has been generally assumed that nuclein wholly escapes peptic digestion. Miescher first obtained nuclein in the residue left after the peptic digestion of pus corpuscles. However, since we have learned that the various nucleins differ so widely in many properties, this question has been re-investigated, with results that do not altogether confirm our previous knowledge. Popoff[1] digested a mixture of acid albumin and yeast nucleinic acid with pepsin-hydrochloric acid. The result was that a portion of the nucleinic acid remained in solution.

A like experiment was made on thymus. This gland, from a calf, was finely divided and separated into three unequal portions. The first portion, constituting about three-fifths of the weight of the entire gland, was digested for one hour with pepsin-hydrochloric acid. The mixture was then filtered, and the amount of phosphorus in both the residue and the filtrate determined after incineration with soda and saltpeter. The residue after extraction with alcohol and ether contained 2.56 per cent. of P. calculated for the dry substance, which weighed 35.5 grams and therefore contained 0.89 grams of P. The filtrate contained altogether 0.243 grams of P. This would indicate that not more than one-fourth of the P. of the thymus passed into solution.

A second portion, constituting about one-fifth of the gland, was submitted to like digestion for two hours. The result was that a greater quantity of the nuclein was thrown out of solution.

A third portion was digested for four hours. This resulted in the precipitation of a still larger per cent. of the nuclein.

Popoff found, however, that nucleinic acid is dissolved in the pancreatic juice.

Gumlich[2] has shown that the administration of nucleinic acid by the mouth is followed by marked increase in the phosphoric acid eliminated in the urine.

The statement of Horbaczewski[3] that the administration of nuclein increases the uric acid eliminated, has been repeatedly confirmed.

In our investigations, as has already been shown, yeast nucleinic acid given by the mouth increases the number of polynuclear white blood corpuscles.

These facts leave no room to doubt the absorption of nucleinic acid from the intestines. However, the dose by the mouth must be very much larger than that required to accomplish a like result given hypodermically. One cannot be certain in a given instance what proportion of that administered by the mouth is absorbed. For these reasons I regard the hypodermic method the more exact and otherwise preferable.

With care, nucleinic acid may be injected intravenously. I have at one time injected 5 c.cm. of a ten-per-cent. solution in this way without any bad results. Intravenous injections are painless, and theoretically this is the ideal method of administration, but a larger number of experiments must be made upon lower animals before the dangers in this method can be accurately measured. Therefore, I do not at present recommend it. I have elsewhere[1], with McClintock and Perkins, reported the employment of very large quantities of solutions of yeast nucleinic acid intravenously in rabbits, and have shown that with care this may be successfully done. Certainly, yeast nucleinic acid differs from leuconucleinic acid, inasmuch as the former does not coagulate the blood when injected intravenously.

Incompatibles.—Quinin and all the coal-tar antipyretics are to be avoided in the nuclein treatment. Atropin is probably physiologically antagonistic to the action of the nucleinic acids, and should not be given for night sweats in the nuclein treatment of tuberculosis.

Effect of Nuclein on Intestinal Fermentation.—Yeast nucleinic acid has a markedly retarding effect upon fermentation in the small intestines, as we have shown by determining its influence upon the conjugate acids eliminated in the urine.

THERAPEUTIC USES OF YEAST NUCLEINIC ACID.

Acute and Sub-Acute Inflammation of the Upper Air-passages.—I have used yeast nucleinic acid in the form of a spray with compressed air for nearly four years, in the treatment of acute inflammations of the upper air-passages as coryza, tonsillitis, pharyngitis, and non-specific laryngitis, and it has given me better results than any other form of medication I have ever tried. I have employed for this purpose the one-per-cent. solution diluted with an equal volume of a saturated solution of boric acid. This preparation has also been of great service in the treatment of hay fever. It has not relieved all such cases, but it has given complete relief to some, has ameliorated others, and has failed to benefit but few. In hay fever, success is rendered more certain if, after spraying the nose, throat, and larynx thoroughly with the above-mentioned preparation, a small amount of a four-per-cent. solution of cocain be employed, also in the form of a spray.

Typhoid Fever.—The action of yeast nucleinic acid on fermentation in the small intestine induced me to try this agent in typhoid fever. I have had no opportunity to use it in any extensive epidemic of this disease. Dr. Harkin[2] of Marquette, Mich., has reported very favorably upon his results with the one-per-cent. solution in an epidemic of typhoid fever at that place. I have used it only in sporadic cases, and as these vary so widely in their clinical history I am not prepared to draw any conclusions from my experience. I think, however, that it is worthy of more extensive trial and would recommend for this purpose drachm doses of the five-per-cent. solution every two to four hours by the mouth.

In Cancer.—I have tried nucleinic acid in three cases of carcinoma of the breast. All of these had been submitted to operation, the cancer had returned, and the cases were inoperable. The treatment was, therefore, employed as a last resort. Injections were made into the healthy tissue around the growth. There was no evidence of beneficial action in any of these. I have employed similar treatment in two inoperable cases of epithelioma. There was no curative action in these. It is true that I did find a wash of nucleinic acid beneficial in these cases of epithelioma, inasmuch as it destroyed those germs which produced a most disagreeable stench. For this purpose I can commend a five- or ten-per-cent. solution as a wash for the diseased surface. In all of these cases, both of carcinoma and epithelioma, the growths were examined microscopically, and there was no doubt of the correctness of the diagnosis. In a case pronounced a sarcoma by some eminent specialists, nucleinic acid apparently wrought a marvelous cure. The patient, the wife of a prominent physician on the Pacific coast, was brought to her home near Ann Arbor in February, 1895, with what was pronounced a sarcoma of the pelvis. She was greatly reduced in weight and strength, weighing 73 pounds, and being unable to walk across the room. In fact, she was unable to sit up. There was a hard tumor, round and, as correctly as I could estimate, three inches in diameter, easily felt through the vagina, and apparently growing out from the ilium on the left side. The one-per-cent. solution of nucleinic acid was employed in the treatment which was administered by her husband. At first the injections were made directly into the growth through the walls of the vagina by means of a specially prepared needle. Later, the injections were made into the gluteal muscles. Treatment was given daily for six months, and then less frequently for some months longer. The strength and weight of the patient gradually increased, and the size of the growth diminished *pari passu.* By the first of July, 1895, the patient weighed more than ever before, and she was able to walk several blocks. Her husband writes me as follows: "In January, 1896, there was some pain in the left side of the pelvis, and a small hardened mass appeared, quite tender and apparently occupying a fold of the broad ligament. Nuclein was used for about two months, injected into the gluteal region. By May, there was no sign of the trouble and an increase of weight was noticed, as well as an improvement of the general condition. At present writing (October 30, 1896) she weighs 123 pounds, which is about ten pounds more than she ever weighed. She is in good spirits and able to perform ordinary duties." Of course, this growth might not have been a sarcoma. The fact that it disappeared so completely is presumptive proof that it was not a malignant growth, but in a similar case I should certainly try the nuclein again.

[2] *Therapeutic Notes*, 1896, p. 30.

Septicemia.—Boise[1] and Hofbauer[2] have reported good results from the treatment of puerperal septicemia with nuclein, the former using my preparation, and the latter that of Hobaczewski. Hofbauer states: "Among the clinical symptoms which were observed during the course of treatment, the following may be mentioned: (1) Effect on the general condition. This was manifested in a very marked and often surprising manner. Patients who previously lay apathetic and half asleep now give a clear and satisfactory answer when questioned as to their condition. Though the temperature remained above the normal, nevertheless the improved appearance and the calm expression of countenance offered a decided contrast to what had previously been observed. At the same time the icteric tint of the skin disappeared, and the appetite was improved. (2) Influences on the local condition. Puerperal ulcers soon took on a healthy appearance and healed. The discharges from the septic uterus rapidly lost their odor and purulent character, and lessened in quantity. The first dose increased the temperature, followed by a gradual decrease. The remissions were longer and more pronounced, and the exacerbations slighter till restoration to the normal resulted.

(To be continued.)

PROLAPSE, PROCIDENTIA, AND INVAGINATION OF THE RECTUM.[3]

BY GEORGE RYERSON FOWLER, M.D.,
OF BROOKLYN:
PROFESSOR OF SURGERY AT THE NEW YORK POLYCLINIC; SURGEON TO THE BROOKLYN, AND TO THE METHODIST EPISCOPAL HOSPITALS.

THE indiscriminate employment of the terms "prolapse of the rectum," "procidentia recti," and "invagination of the rectum" has given rise to some confusion in the minds of writers and practitioners regarding these conditions. In the present consideration of the subject the term prolapsus will be restricted to the protrusion of otherwise healthy mucous membrane outside the anus, and this to an extent which shall not include the entire circumference of the bowel. This definition excludes those cases in which internal hemorrhoids make their appearance beyond the anal margin, and reserves for the term "procidentia" the cases in which the entire circumference of the bowel is protruded. Ordinary internal piles may be prolapsed, but, as a rule, this is limited to the pile-bearing area of mucous membrane; under these circumstances the protrusion may involve the entire circumference and yet not be properly included in the term prolapse of the rectum. In procidentia recti the mucous membrane from just within the anal orifice, or this together with the submucosa and muscularis, may appear outside the anus (Allingham). Finally, a condition of invagination occurs. The upper portion of the rectum may descend through the lower part, after which it may or may not make its appearance outside the anus, according to the degree of laxity of the connective tissue. In the first instance the condition would be that of invagination with procidentia, and in the second that of invagination alone.

The chief predisposing cause of the production of these affections is a relaxed condition of the muscular and connective tissue structures of the bowel. Involvement of the submucous connective tissue alone will lead to simple eversion of the mucous membrane, a condition which is not infrequently observed in health, and an exaggeration of which, under the influence of some exciting cause, such as straining at stool, may lead to the pathologic condition known as prolapse. A relaxation of the muscular tissues, in addition, leads to a protrusion of both the entire thickness and circumference of the rectum, and it is only a question of time, when this stage has been reached, when the peritoneal covering of the bowel will have also descended sufficiently to protrude through the anus (invagination and procidentia combined). As an additional factor in the production of prolapse and procidentia, the weakening effect of the loss of connective tissue support upon the muscular apparatus of the rectal outlet must be taken into account. Both the sphincters and levator ani become involved in the pathologic process, and the loss of support which this entails still further increases the tendency to prolapse and protrusion of the superimposed bowel. It is a significant fact that, even in the early stages of these conditions, the finger introduced into the rectum does not, as a rule, meet with that resistance characteristic of the action of the anal sphincters in health. Finally, an abnormally long mesentery has been suggested as a possible predisposing cause. In the normal condition the peritoneal covering of the second portion of the rectum is restricted to its anterior surface, the posterior portion being secured to the sacrum by connective tissue attachments. Under conditions of abnormal development this portion of the gut may be likewise covered with peritoneum, an abnormally long meso-rectum resulting (Allingham).

---

[1] "The Treatment of Puerperal Septicemia." Transactions of Mich. State Medical Society, 1896.

[2] *Centralblatt f. Gynæcologie*, 1896.

[3] Read before the New York State Medical Society, Albany, January 27, 1897.

Henoch[1] regards the symptoms under discussion as due to an invagination of the lower bowel in miniature. The lower portion of the rectum is more markedly muscular than that which lies immediately above, which is wider and more lax. The latter again merges into a portion above which is supplied with stronger muscular circular fibers. This last mentioned portion, through contractions of its muscular fibers, is capable of inverting and pushing the middle lax portion down to the anus, from which it finally protrudes.

The experiments of Nothnagel[2] are of interest in this connection. This observer applied a faradic current to a portion of the bowel, and was thus able to produce an invagination by the resulting tetanic contractions. The portion of the bowel in the direction of the anus, which still maintained its normal lumen, was now drawn up over the circulatory contracted portion by muscular action, probably that of its longitudinal fibers. In this artificial production of invagination the tetanic contraction of the gut at the point of irritation serves to fix the place where the invagination begins.[3]

The principal exciting causes during childhood, at which period of life these symptoms are most likely to occur, are conditions of constipation, as well as diarrheal and dysenteric affections, the presence of a rectal polypus and certain forms of ascarides, all of which produce more or less rectal tenesmus. With the occurrence of a certain amount of eversion of the mucous membrane the presence of this acts as an irritant, and provokes still further expulsive efforts after the exciting cause has ceased to exert its direct influence. The yielding of the submucosa, under these circumstances, may only result in comparatively slight prolapse; or, if the preëxisting degenerative changes are pronounced, and particularly if these involve the muscular apparatus to a marked degree, procidentia, and finally invagination, may follow. Adhesions between the reflected layers of the balenopreputial mucous membrane (phimosis), by offering obstruction to the free flow of urine, aided possibly by reflex action, may serve as an exciting cause. In adults, vesical tenesmus incident to the presence of an enlarged prostate, stricture of the urethra, or a vesical calculus, serve as exciting causes. In these diseased conditions of the urinary viscus and its outlet, the muscular apparatus of the ano-rectal orifice becomes weakened by the more or less constant expulsive efforts, with final impairment of their restraining function. Finally, cases occur in which no well defined exciting cause can be determined. Degenerative changes affect the connective tissue attachments of the bowel, the muscular structures, and the final mechanism of the production of the prolapse is incident to the normal efforts of defecation.

The underlying pathologic changes which serve as a basis for the occurrence of the symptoms under consideration are not well understood. Owing to the well known looseness of the submucous connective tissue attachments of the walls of the rectum, it is probable that slight mechanical causes will produce prolapse, and that degenerative changes occur in the muscular and fibrous structures of the floor of the pelvis which support the contents of the latter in their normal position, which serve to lay the foundation for the final stages of the condition. Whether or not the paretic involvement of the sphincters is a result of fatty degeneration due to neural or vascular disturbances occurring in connection with degenerative changes in the connective tissue, or follow as a legitimate result of the pressure of the loosened mass which is gradually being forced down and through the anal orifice from above, is a question that must be considered as still *sub judice.* Chronic inflammatory conditions with infiltration and thickening of the involved structures may occur at any time in the history of the affection.

From what has already been said of the nature and mechanism of production of prolapse, procidentia, and invagination, the clinical appearances may be easily comprehended and the diagnosis made. While these conditions may be met with at any period, they are most apt to occur at the two extremes of life. Simple prolapse is most frequent in childhood and procidentia is most frequently observed in those of advanced years. The first onset of the prolapse may be sudden, in which case it is due to some excessive straining effort. More frequently, however, the onset is gradual, the mucous membrane becoming at first prolapsed, procidentia, and finally invagination occurring as later stages of the condition. In simple prolapse the tumor is small in size, and the protruding mucous membrane appears as bright red folds, between which sulci radiate from the aperture. This is due to the fact that the entire circumference of the bowel is not involved, the principal masses being placed laterally. In procidentia the tumor is much larger, and the sulci are arranged in a direction parallel with the anal margin. The protrusion, in the beginning, occurs only after defecation, and is easily replaced and retained until another act of defecation forces it out again; later on it reappears in the interval, and, owing to the infiltration of the mucous membrane and submucosa, and the resistance offered by the sphincter, complete replacement is not always easily accomplished. Usually, however, thickening of the parts and weakening of the muscular apparatus advance *pari passu*, until finally the mass is more easily returned than it is retained. Friction of the clothing, or T bandage usually worn to support the mass, results in abrasion of the mucous membrane, from which bleeding may occur; trophic disturbances may lead to ulceration. In addition, both a mucopurulent discharge and anal bleeding may occur without constant protrusion of the mucous surfaces. In advanced cases constipation and diarrhea alternate. Fecal incontinence may be present. More or less pelvic distress is complained of, and in some cases pains in the loins and thighs. In males, the dragging upon the bladder and urethra may produce difficulty in micturition.

[1] *Vorlesungen über Kinderkrankheiten*, 4th edition, Berlin, 1889, p. 527.

[2] *Specielle Pathologie und Therapie*, Bd. 18, p. 298, Wien, 1896.

[3] *The International Medical Annual*, 1891, p. 419.

The diagnosis may be confirmed by an inspection of the parts. While the protrusion of internal hemorrhoids is usually associated with more or less prolapse of the mucous membrane covering the sphincters, and in some instances that which lies immediately above, this condition can be easily differentiated from true prolapse. The presence of hemorrhoidal tumors, with their livid color, as well as an increased firmness of the mucous membrane, are such striking signs that there can be no excuse for error in this particular. In the case of a child, a polypus may complicate the diagnosis. This, however, may be usually isolated, and its base of attachment identified. In children, a colo-rectal invagination may occur independently of a prolapse or procidentia. In such cases, the occurrence of sudden pain, with symptoms of collapse, intestinal obstruction, and the passage of blood and mucus preceding the appearance of a protrusion at the anus, will prevent the two affections from being confounded. In incomplete or partial prolapse, and before the occurrence of complete relaxation of the sphincters, vascular stasis of an imprisoned portion of the mucous membrane of the bowel may result from efforts at contraction of the irritated muscles, and sloughing of the parts follows. On the other hand, relaxation of the sphincter to the stage of complete insufficiency may precede the occurrence of the gangrene, in which case the latter is to be attributed to trophic nerve disturbances, or inflammatory stagnation (endarteritis obliterans). This process of circular sloughing constitutes one of nature's efforts at cure.

In procidentia recti both serious and important complications may occur. In invagination, the involved peritoneum sometimes becomes the seat of inflammatory changes, which are followed by obliteration of the peritoneal pouch. In simple prolapse this adhesive inflammation does not occur, and the protruded portion of the peritoneum retains its relations with the general peritoneal cavity. The pouch of peritoneum may be the sac of a hernia and contain portions of small intestine, an ovary, and, exceptionally, the bladder. Even other viscera have been found similarly involved. The intestine may become strangulated in the sac, and an "anus preternaturalis in ano" result (Esmarch). Spontaneous rupture of the rectum may occur as a complication. In cases collected from the literature by Quénn, no history of ulceration preceding the rupture was obtained. In one case which came under the personal observation of this surgeon, microscopic examination revealed inflammatory changes in the rectal tissues.

In view of the fact that the conditions usually occur in weak and feeble children and in debilitated adults the exhibition of tonics, and change in the habits and occupation of the patient, are indicated, and constitute appropriate measures of treatment. The diet must be regulated and constipation avoided. Moving the bowels in the recumbent position will sometimes prevent the occurrence of the prolapse. When the affection is due to any of the remediable exciting causes mentioned, such as the presence of a contracted prepuce, rectal polypus, parasites, stone in the bladder, or any condition of the urinary outlet producing straining efforts, these must be first removed before a cure can be brought about. Reduction may usually be accomplished by the patient himself, if an adult, in recent cases. If the surgeon is called in, with the patient in the knee-elbow position he may succeed by spreading a round piece of dry lint or coarse table linen over the protruding mass, and, after oiling his fingers to facilitate its subsequent withdrawal, push the mass, linen and all, into the rectal cavity. If this fails he may roll a small square of paper into the shape used by grocers in making cone-shaped packages, and after oiling its interior, place the apex of the cone in the sulcus, introduce his finger in its interior, and by steady pressure reduce the protrusion and at the same time force the cone into the rectum. The lint or paper cone may remain until the next act of defecation. If it becomes necessary to employ an anesthetic, the surgeon should be prepared to carry out one of the methods of radical cure. After reduction the buttocks should be strapped together with broad and long strips of rubber adhesive plaster to prevent reprotrusion. Cold water enemata are sometimes of service in preventing recurrence of the protrusion. Astringent injections are of but slight benefit, and may increase the irritation. If, in spite of these measures, the condition persists in its return with each act of defecation, methods of radical cure are to be considered. Bryant[1] recommends physiologic rest, by making an artificial anus in the left groin, and placing the patient in the recumbent position for two weeks, the artificial anus being afterward closed. It does not seem to me necessary to subject the patient to the dangers of two operative procedures involving the peritoneal cavity, to say nothing of the miseries incident to incontinence of feces in an abnormal direction, when simpler and equally efficient measures are available.

In children the method of linear cauterization introduced by Van Bruen gives the best results. After thoroughly emptying the bowels, an anesthetic is administered. The mucous membrane is lightly touched in narrow longitudinal strips with the cauterizing iron, after which the mass is reduced. The bowels are kept confined two or three days with opium in small doses, and the first movement preceded by a liberal enema of sweet oil. Allingham cleanses the protruding mucous membrane and applies nitric acid. The patient is kept in the recumbent position for from four to six weeks, and no bowel movements are permitted to take place in other than this position.

While the two last-named procedures are frequently successful in children, and even in adults in simple cases, it frequently becomes necessary to resort to less conservative measures in order to obtain a permanent cure. Among those introduced in recent years are to be mentioned temporary narrowing of the anal aperture by means of a purse-string or tobacco-pouch suture; narrowing of the lower portion of the rectum by infolding of its posterior wall; narrowing by means of excision of one or more elliptical portions of the mucous membrane alone, or this combined with narrowing of the anal orifice; by combined narrowing and shortening of the prolapsed portion by the application of Gersung's operation for fecal incontinence following excision of the rectum for carcinoma; elevation and fixation of the prolapse either extra- or intra-peritoneally; and, finally, amputation of the protrusion.

Temporary narrowing of the anal aperture by means of a purse-string suture was applied by Platt,[1] as follows: "At the junction of the skin and mucous membrane, just beneath the latter, a curved needle is inserted in the median line below, and a silk thread carried half way around the anus and out again, in the median line above, re-inserted in the same opening and brought out at the first puncture, making a purse-string suture. The little finger is then put in the anus and the purse-string tied around it. Apparently this would cause a suppuration and possibly a fistula. It does nothing of the kind, nor does it cause any pain afterward. The child has its stools in the recumbent position. If the feces are at all hard, injections are given to soften them. After three weeks the suture is withdrawn and the place kept clean, when it heals immediately with no return of the prolapse. By this method the bowel is kept in place long enough to contract adhesions." The operator further remarks that "two weeks after the removal of the suture in these cases one could not tell that sutures had been passed." It is probable that this procedure will prove of value as supplementary to Van Buren's and Allingham's method, and the combination bids fair to supplant more formidable measures in properly selected cases.

Infolding of the posterior wall of the rectum was proposed and successfully carried out by Lange of New York as follows: The patient was anesthetized and secured to the table in the knee-chest position, with the head turned to one side to permit of the anesthetic being continued. An incision was made as for the removal of the coccyx, and the latter removed. Through the space thus gained the rectal wall was infolded in a longitudinal direction, and there held by two rows of buried "*etage*" sutures of catgut. The first row was applied near the median line, and was so placed as to form a fold in the posterior wall of the bowel which projected into its interior. The second row brought the lateral portions of the bowel wall over the first, thus increasing the depth of the fold. The divided edges of the levator ani and external sphincter were finally united. The wound of the skin was partially sutured and the cavity corresponding to the excised coccyx loosely packed with iodoform gauze.

Excision of portions of the rectal mucous membrane has succeeded in certain mild cases. The excised portions are lozenge-shaped, and so arranged that the resulting eschars are longitudinally placed. Two or more of such elliptical excisions may be applied, according to the size of the prolapse. In more advanced cases it will be necessary to narrow the external orifice in addition, either by the application of the purse-string suture or of Roberts' operation. The last named surgeon makes a diamond-shaped excision, one-half of the space included in the excision being upon the mucous membrane of the posterior wall of the rectum and the anal opening, and the other upon the skin between the latter and the coccyx. The anus is dilated preliminarily. These incisions are deepened and the included tissues removed, the removal including in that portion of the diamond upon the rectal wall the entire thickness of the latter, and in that upon the skin the integument and subcutaneous connective tissue. At the point where the bases of the two triangles which form the diamond-shaped space meet about one inch of the sphincter ani is removed. The whole is excised in one piece. The upper limit of the space left is situated about three inches up the bowel, and the lower posterior limit of that located externally at the point of the coccyx. The space left is closed by silk sutures except at the point of the coccyx, where a drainage tube is introduced. The ends of the anal sphincter are still further secured by a deeply placed and shotted silver wire suture.

[1] *Johns Hopkins Hospital Bulletin*, July, 1896.

Gersung's method of torsion of the stump of bowel left after excision of the rectum for carcinoma in order to obtain a sphincter action at the rectal outlet may be applied for the cure of prolapse of the rectum. The lower segment of the bowel, together with the sphincters, is loosened from all connections, the mass reduced and torsion practised. A half turn of the bowel upon its long axis may produce sufficient narrowing and shortening to effect the purpose, or an entire turn, or even more, may be necessary. The skin wound is closed, this being sufficient to retain the twist, and a small drain introduced posteriorly.

In the operations by elevation and fixation the object is to suspend and secure the prolapsed portion in position. Verneuil aims to accomplish this by the extra-peritoneal route. Maylard,[1] in his excellent treatise, gives the preliminary incisions of this operation as follows: "A calculation is first made regarding the dilated anus as to the extent of the boundary necessary to produce a normal-sized aperture. From points equidistant from the median line, and where it is believed the remaining anterior part of the anal circumference contains a sufficient margin when united to form a normal orifice, incisions are carried horizontally outward for 3 cm." The further steps of the operation are as follows: "From the points where these incisions terminate two other incisions pass to meet each other at the point of the coccyx. The flap thus formed is loosened from behind forward, and left temporarily attached to the tissues surrounding the anus. Access is thus gained to the space between the rectum and coccyx. The posterior wall of the rectum is loosened for a breadth of from 5 to 6 cm., and to a height corresponding to the distance from the anus to the coccyx. Four threads are now passed transversely through the posterior wall of the rectum, parallel with each other, and not including the mucous membrane. By means of a needle with an eye at the point, which is passed through the skin from without, the threads are drawn through and secured upon the skin surface in pairs upon either side of the median line. Strong traction is made upon the sutures in order to secure the rectum in its new position. Rolls of iodoform gauze are placed upon the skin beneath the loops in order to prevent these from being buried. The upper suture should be on a level with the articulation between the first bone of the sacrum and the coccyx, and the lower at the point of the coccyx. The intervening sutures are placed about equidistant between them. The triangular-shaped flap is now removed, the muco-cutaneous anal margin being preserved, a drainage tube introduced, and the wound closed by sutures.[1] In another account of the operation [2] translated by Maylard, it is stated that the flap is not removed, but replaced and sutured.

In a case successfully operated upon by myself, I modified this operation by making the incision semicircular in shape and half way between the anal margin and the point of the coccyx. The dissection is carried well up between the rectum and sacrum. With two fingers in the rectum, the posterior wall of the latter is forced through the external wound, and four sutures of heavy chromicized catgut passed transversely through the posterior rectal wall, including all its tissues, to the mucous membrane. A short incision is then made down to the bone at the junction of the sacrum and coccyx, and the sutures brought out upon corresponding sides of the latter and tied across the bone, strong traction being made to bring the rectum in position. This skin wound is now closed. The incision between the point of the coccyx and the anus is now closed, except at the central portion, in which an iodoform gauze drain is inserted. A further improvement would be to pass the sutures through the posterior wall of the rectum, so as to produce an infolding effect, as in Lange's operation, by drawing the lateral portions of the rectal wall to the median line and there securing them by tieing. The long ends of the same sutures may now be used for suspending and fixing the rectum.

McLeod secured fixation of the bowel above Poupart's ligament by pushing up the gut from below by means of the left hand in the rectum, and there securing it by two long acupressure needles passed three inches apart through the abdominal wall and the gut, guided by the fingers in the bowel, and then out again upon the abdominal wall. He then made an incision between the needles and down upon the peritoneum. Guided by the fingers again passed into the rectum for that purpose, he attached the serous and muscular coats to the abdominal wall by silk sutures. The wound in the abdominal wall was then closed by silk sutures, which also included the two outer walls of the intestine. The steel pins were removed in twenty-four hours.

Medical Society, reported three cases upon which he had operated by abdominal incision, as in iliac colostomy. After opening the abdomen, the prolapse was reduced by drawing up the sigmoid flexure and upper portion of the rectum, in which position the gut was secured by silk sutures passed through the entire thickness of the meso-rectum and parietal peritoneum.

Finally, extreme cases of procidentia recti will occasionally come under the surgeon's observation in which nothing short of a removal of the parts will avail to rid the patient of an otherwise never-ending source of misery. In pre-aseptic days amputation of the protruding mass almost invariably terminated fatally from peritonitis. At the present time, however, these operations are not only justifiable, but are imperatively demanded, when other and less extensive measures fail to afford relief.

Operations designed for the removal or amputation of the protruded mass of intestine may be performed aseptically, and a strict regard for this part of the operative technic should always be observed. All operative procedures in this region should be preceded by a few days purgation with salines, during which time the patient should be fed with sterilized liquid food. In the operative procedures about to be described, both the cavity of the bowel and the peritoneum are invaded by the surgeon's knife, and increased caution is necessary in the manipulation, lest the peritoneal cavity be soiled by infectious material. The protruding portion of gut should be well washed with soap and warm water before making the incisions, the parts being well protruded by the patient for that purpose before anesthetization, and during the operation the parts are to be constantly irrigated with a weak solution of carbolic acid or the borosalicylic solution of Thiersch. The best position for operating is the lithotomy position, and in order to secure gravitation of the abdominal contents away from the seat of operation, the pelvis should be well elevated. All bleeding points are to be secured before returning the sutured parts and an opium and iodoform suppository introduced. The bowels are to be kept confined for from five to eight days, in order to secure firm union, and, that there may be no risk of tearing the latter apart, the first bowel movements are to be made as easy as possible by a copious preliminary injection of sterilized sweet oil. The cavity of the rectum may be likewise advantageously washed out during the first few days by means of copious enemata of sterilized water following each movement of the bowels.

In Mikulicz's operation[1] the intestine is fixed by two strong sutures passed through the most dependent part of the protrusion; these are given in charge of an assistant. A transverse incision is made in the anterior face of the portion of gut which presents itself to the surgeon, or that portion which lies externally. This incision is made from 1 to 2 cm. in front of the supposed site of the anal opening. Bleeding vessels are secured singly and ligated with catgut. When the external portion of the intestinal tube is completely cut through the peritoneal pouch between the two portions of the gut is opened and the peritoneal covering of the internal intestinal tube exposed. The communication with the peritoneal cavity is shut off by suturing the peritoneal surfaces together as fast as the transverse incision is extended, the surgeon extending the latter and placing catgut sutures in position as he proceeds, until the entire circumference and thickening of the external portion of the intestinal tube is divided. This being accomplished, the internal intestinal tube is divided just in front of the row of sutures already applied, and the two extremities of the gut united by a second row of sutures which includes all the coats of the intestine. Mikulicz employs silk for this second row of sutures and leaves them long to steady the bowel during the subsequent steps of the operation. Chromicized catgut may be employed with advantage, and the difficulties of finally removing the sutures avoided. In order to prevent the line of union from slipping away from the operator during this portion of the manipulation, the stumps may be grapsed with several pairs of fixation forceps. Finally, the line of sutures is to be dusted with iodoform and the remainder of the gut is replaced.

Kleberg[1] encircles the part just above the line of proposed suturing with an elastic ligature drawn sufficiently tight to control the circulation, makes a 2-inch longitudinal incision which opens in the sac formed by drawing down the peritoneum and thus assures himself that the sac is empty. A trocar is then plunged from before backward through the sac, and through this two elastic ligatures are passed through the protrusion and the two halves of the latter tied off. The temporary ligature is then removed, after which the prolapsed portion is amputated below the suture line.

Treves[2] operated in a case of simple prolapse as follows: The first circular cut was made through the mucous membrane only. He then dissected the latter off and turned it down like a cuff until the external sphincter was exposed, at which point the remainder of the protrusion consisted of mucous membrane only.

The latter was then divided at the level of the anus and the stump of mucous membrane was sutured to the skin margin. The peritoneal cavity was not opened. In a case of procidentia he was compelled to open into a peritoneal pouch which had been dragged down. This was immediately closed with chromicized gut, and the divided end of the bowel sutured to the anal margin by sutures which involved the whole thickness of the wall of the gut and as much as possible of the subcutaneous tissue about the anus.

Esmarch[4] proposes the following operation in severe cases: A wooden bougie with a circular groove is introduced until the groove has almost reached the anus. The prolapsed portion is then made bloodless by an Esmarch bandage, and constriction is made by passing an elastic band around the tube. Provision against hemorrhage being thus provided for, the parts are amputated almost an inch in front of the elastic band. All visible vessels are ligated and the peritoneum carefully closed by catgut. The constricting band is now removed and bleeding points secured, after which the remaining coats are sutured and the tube removed and supplanted by a rectal tube.

GAUZE DRAINAGE IN SURGICAL GYNECOLOGY.

By WILLIS E. FORD, M.D.,
OF UTICA, N. Y.

Gauze has so generally superseded the other means for draining cavities and wounds of various kinds, that it is not the purpose of this paper to institute any comparison between this and other forms of drainage, but to discuss some of the methods of its use which have been found to be of service in the hands of various operators.

When extensive surfaces are left to ooze, and especially within cavities where complete apposition cannot be secured, gauze acts like multiple capillary tubes to remove the serum that would otherwise separate the tissues while the oozing is at its most active stage. Iodoform gauze has come to be pretty generally used for this purpose, though it is doubtful if the iodoform in all instances is necessary. This gauze is, however, a styptic, and acts more favorably in preventing capillary bleeding than does plain gauze. Where quantities of gauze have to be used, as in packing the pelvic cavity when extensive denudation of surfaces has occurred, there is more danger of iodoform poisoning from the direct absorption of the drug than is commonly supposed. Such absorption has occurred many times to such an extent as to produce alarming and even fatal symptoms, and I am convinced that in many other cases a less degree of the poisoning occurs which proceeds no further, perhaps, than to cause headache, restlessness, and rise of temperature.

Iodoform is not an antiseptic, and does not make an infected wound clean, but the gauze mechanically retains pus for a short time within its meshes, and the iodoform seems to retard the septic process by rendering the pus temporarily inactive until nature can throw about it a wall which shuts the cavity off from adjacent tissues. When iodoform gauze is used for packing a uterus that has been curetted, unless the wound has been made aseptic, or nearly so, previous to the packing, there will be a prompt rise of temperature and all the evidences of infection if the gauze is not speedily removed. · To rely, therefore, upon iodoform gauze to make an incomplete operation a success is a fallacy, and has brought the method of tamponing the uterus after curetting into disrepute in certain quarters. Anyone can see how a purulent salpingitis can be made more dangerous than it originally was by tightly packing the uterus with gauze. In this case the incorporation of iodoform in the gauze will not help matters, and ought not to be expected to. So safe and so conservative a thing as gauze tamponing may be, and often is, so thoroughly misapplied in these cases as to bring the soundness of the theory into question. No one can doubt, I think, that careful tamponing with gauze after curettement for chronic metritis aids very much in bringing about the involution of the organ, which is one of the chief things to be sought for. The cavity must never be tightly packed, however, unless it is aseptic, and likely to remain so, because there is no drainage of pus into it, and this whole question, therefore, hinges upon the diagnosis, which ought to be carefully made in all instances.

As to the length of time that gauze should be allowed to remain in the uterus there is a great difference of opinion. My own rule is to leave it five days, unless there is a rise of temperature and severe pain. If the gauze has remained within the cavity for that length of time it seems to me that all the good has been accomplished that can reasonably be expected, and I do not replace it. I prefer, if involution does not then occur, to rely upon douching, iodin and glycerin tampons, and galvanism. It seems to me better to wait two months even, and then to dilate and curette, if necessary, and to thoroughly apply the tampons under ether, than to do this immediately after the first removal. The objection to gauze tamponing within the uterus which has lately been urged—that it acts as a wedge in the cervical canal as soon as the uterus contracts, and thus acts as a plug to prevent drainage—I think is an error, for it is difficult to suppose that only the longitudinal fibers of the uterus thus contract and serve to force the gauze firmly downward. The truth is that gauze should never be so firmly packed that such obstruction can take place. Practically, such a difficulty has never occurred to me, perhaps from the fact that in all cases where moderately firm packing has been used, a little of the tape, say six inches or a foot, is drawn downward daily after the first forty-eight hours, and free drainage of the uterus thus secured.

---

[4] Liefering, *Deutsche Chirurgie* 48. Review by Kammerer, "Annals of Surgery," vol. vii, page 151.

The next objection urged—that the gauze tampon does not secure drainage, and is, therefore, a danger in cases of catarrhal salpingitis—has more force; but in these cases, too, accidents occur by reason of the firm and consequently improper use of the packing, especially over the mouth of the Fallopian tubes. All this is easily avoided by a little skill, and the gauze drain, when loosely applied, seems to more effectually bring about subinvolution of the uterus than can be secured without any drainage. In these cases it is of still more importance to pull down the tape little by little, until one-half of the whole amount has been removed, previous to its complete removal.

The third objection—that curettage is always followed by a higher average temperature when gauze is used as a part of the operation—is not borne out by the facts as I have observed them. When the scraping has necessarily been vigorous, and a large amount of adenoid tissue has been removed, there is often a rise of temperature of one degree, which is of but short duration, and which, I think, is due to the mechanical violence, rather than to the presence of the gauze; and this, in my opinion, is proved by the fact that the temperature soon subsides, and, after the first day, is not above normal.

Introduction of gauze into the uterus during the active stage of gonorrheal inflammation is wrong, and, in addition to the danger of increasing the salpingitis, can accomplish no practical good. The distension and packing of the vagina in these cases is certainly very beneficial, for while smoothing out the rugous membrane, it keeps the parts dry, and thus prevents rapid prolification of germs. My practice has been, in these instances, as well as in others where there is a profuse vaginal discharge, to introduce sterilized gauze, upon which I pour, as it is passed into the vagina, an abundance of powdered boric acid. These tampons are left in place for thirty-six, or even forty-eight hours, and are effectual not only in stopping the catarrhal exudate, but also in preventing that troublesome pruritus which accompanies so many of these conditions.

In plastic operations upon the vagina, dry gauze, preferably bichloridized, is useful in not only rendering aseptic such secretions as cannot be avoided from above, but also in keeping dry the parts, so that the wound may be sealed up as speedily as possible. Since I have adopted the rule of curetting and tamponing in every case before a trachelorrhaphy is performed, I have found the results to be much better than when this operation was done without it. Involution is much more generally secured, and the wound becomes firm in a shorter time. Of course, dry gauze is loosely packed in the vagina and closely around the cervix. In cases of septic metritis following abortion, or retained placenta after childbirth, I have also been accustomed to drain, but never to pack the uterus firmly and never to allow the drain to remain in more than forty-eight hours. If the purulent discharge is very abundant, the drain is not put in at all during the first few days, during which time warm antiseptic irrigation is used. When the temperature has fallen, and the irrigation is no longer necessary, the gauze may be introduced and removed daily.

Of late I have been experimenting with other kinds of gauze, especially in the treatment of those hopeless cases of inoperable cancer, which require rigid antisepsis in order to make the life of the patient tolerable. After curetting such a dirty cavity, irrigating, and applying chloride of zinc, I have packed these wounds with gauze saturated in acetanilid solution, and have found that the pain is much less, as well as the fetor, and that the gauze can remain in fully as long as we are accustomed to leave iodoform gauze. The acetanilid acts well also as a styptic, and I am using it more and more in sensitive sinuses of all sorts. The combination of odors made by these discharges with iodoform is something particularly sickening, and I think that for this reason alone acetanilid gauze should be used exclusively in these cases. Within the past month I have learned of one dispensary case in which the uterus was tamponed with acetanilid gauze for hemorrhage and the patient sent home, the operation being followed by syncope, profuse sweating, and prolonged vertigo, which seemed to be due to absorption of the drug. In cases of cancer, however, or of sloughing wounds generally, this absorption need not be feared.

In all cases of vaginal celiotomy gauze drainage seems to be necessary. It acts not only as a drain, but the gauze keeps the wound open, which would otherwise speedily close, and it also prevents the occurrence of hernia. But aside from the common uses of the drain in these cases, when the peritoneum is actually opened and pus is found, there are instances in which the introduction of the gauze into the phlegmonous mass sets up a drainage which soon causes the disappearance of the exudate. This use of iodoform gauze is one of the most direct illustrations of the benefits of capillary drainage. Such gauze may be left in place for five or six days, and then careful irrigation should be used, after which it should be reinserted. In abdominal operations, when pus has escaped into the pelvis during the removal of diseased tissue, I have for two years employed gauze drainage without irrigation. If the intestines have been carefully protected by sponges, so that the pus has not been freely admitted among them, I have wiped the cavity dry and tamponed with iodoform gauze (two per cent.), then have removed the sponges, and without more disturbance of the viscera than was necessary, have allowed the probably infected tissues to rest against the column of gauze which is brought up out of the abdominal wound. The wound is then closed to within an inch or an inch and one-half of its length. If the gauze has been folded backward and forward when it is first applied, its removal is comparatively easy, and the danger of hernia slight; indeed, I have had no case of hernia from this cause. After the second day the removal of the packing is begun, and strip after strip is removed every day. When the final enclosing tube of gauze is brought up out of the wound there will be found among its meshes detritus to the amount of half an ounce, in many instances chiefly composed of pus corpuscles. What applies to pelvic surgery applies with even greater force to the operation for appendicitis.

Unless the cavity is found to be walled off from the general cavity of the abdomen, irrigation should not be used, for septic material may be carried among the intestines, and beyond the possibility of drainage. Such detritus, if kept within a small field, may be partially removed by wiping with gauze, and the remainder can then be allowed to drain into the meshes of the gauze by the current of fluids caught up by capillary action.

Gauze that is used for external dressing on aseptic surfaces need not be medicated; indeed, the exclusion of air and the prevention of the accumulation of moisture about the wound is all that is necessary. It need hardly be said that all gauze should be most carefully prepared and sterilized, and that for all practical purposes iodoform gauze and bichlorid of mercury gauze should not have such a large percentage of the respective drugs rubbed into the fabric as is usually done by manufacturers.

Antitoxin for Lockjaw.—The cure of a case of lockjaw, after fifteen days' treatment with the tetanus antitoxin prepared by the New York Board of Health, is reported at Bellevue Hospital. It is the first cure of tetanus by this treatment at Bellevue, and the second in the city, the first was effected at the Presbyterian Hospital June, 1896.

THE RELATION OF MASTURBATION TO INSANITY, WITH REPORT OF CASES.

By RALPH A. GOODNER, M.D.,
OF ANNA, ILL.;
PHYSICIAN TO THE ILLINOIS SOUTHERN HOSPITAL FOR THE INSANE.

That masturbation is both a cause and result of mental disease cannot be gainsaid. There are many more resultant than causative cases, as many insane patients are addicted to the practice after becoming insane who were not so previously. The act is practised among the patients confined in our insane hospitals to a greater extent than we are aware of, in spite of all effort to prevent it on the part of officials and attendants. When we consider that these patients have no opportunity for the normal gratification of the sexual desire, and that in many this desire is abnormally developed, as in the satyriasis of mania and early stage of paresis, it is not to be wondered at.

The deleterious influence resulting from masturbation acts both physically and mentally, but the latter effect is, in my opinion, decidedly the more pronounced of the two. A cause, to be psychical, does not necessarily have to produce an immediate effect, but usually we find such a cause acting through a series of attacks upon the brain and nervous system until mental impairment or disease follows. Some authorities on genito-urinary diseases take the view that the harmful results of masturbation are evident only in those who practice it excessively, and claim that the act in itself is no more harmful than the normal sexual act. While I believe that they who masturbate do so excessively in many instances, I believe also that the results are more baneful, not because of the excesses indulged in, but because the practice produces a direct deleterious effect on the brain and nervous system that the normal sexual act does not produce.

Masturbation can be, and often is, the sole exciting cause of insanity. The four cases I report herewith are only about one-fifth of the total number of insane male patients admitted to the Illinois Southern Hospital for the Insane during the past four years whose histories previous and subsequent to admission showed this habit to be the sole exciting cause of their insanity.

In classifying mental diseases, authorities of today do not recognize any special form as being due to masturbation, although the older writers did, and termed such "masturbatic insanity." While those psychoses due to or accompanied by this vice seem to have certain characteristics in common, I do not think we are justified in classifying them separately. From the description of masturbatic insanity given us by the older writers, I think I recognize the stuporous insanity of the present, and in my experience a great majority of the cases of mental disease resulting from masturbation exhibit this form of the disease, although it is also produced by altogether different causes.

The prognosis of insanity due to masturbation is usually very favorable. The first and most important step in treating such a case is to remove the cause. Any condition that tends by reflex action to direct the patient's attention to his genital organs, such as a disordered condition of the bladder or rectum, and non-hygienic local conditions, must be corrected. I do not know of any drug that possesses any special virtue when directed against this habit, but nervines and tonics are often beneficial, and one should meet any special symptoms as they arise. A proper and nutritious diet should be prescribed, and the bowels kept in a soluble and regularly acting condition. An intestinal disinfectant often seems to be beneficial.

CASE I.—R. B., male, single, aged nineteen; weight, 124 pounds; height, 5 feet 7 inches. Admitted September, 1894; first admission. Occupation, laborer. Duration of insanity not stated. No history of heredity. No bad habits other than masturbation. Physical condition poor. Refused food. Diagnosis, stuporous insanity. Marked and rapid improvement followed treatment, but several remissions occurred before recovery, being due in each instance to a withdrawal of the mechanical means employed to prevent masturbation. Discharged as cured in January, 1895. No recurrence to date.

CASE II.—E. J., male, single, aged nineteen; height, 5 feet 7 inches; weight, 143 pounds. Admitted April, 1893; first admission. Occupation, laborer. Duration of insanity, two months. No history of heredity. No bad habits except masturbation. Physical health good. Diagnosis, stuporous insanity. Patient recovered, and was discharged in October, 1893. No recurrence.

CASE III.—B. M., male, single, aged twenty-five years. Occupation, laborer. Admitted November, 1893; first admission. Physical health good. No heredity, and no bad habits except masturbation. Duration of habit not stated. Diagnosis, stuporous insanity. Patient discharged, cured, in April, 1895. No history of recurrence to date.

CASE IV.—C. W., male, single, aged twenty-two years. Occupation, farmer. Duration of insanity, two months. Admitted November, 1893; first admission. Physical condition good. No heredity or history of any bad habits other than masturbation. Diagnosis, acute melancholia. Discharged cured, in June, 1894. No recurrence.

Three of the four cases presented the same form of insanity, and this form has been present, when the ascertained cause has been masturbation, in about the same proportion in all the cases admitted during the past few years. In these cases not one presented a history of heredity, the great predisposing cause of insanity, or of any other predisposition to the insane state. The remissions in Case I., following so quickly and regularly after the withdrawal of the means to prevent masturbation, the patient at the time being in good physical health, with the absence of a history of heredity, tends to show that masturbation can be the sole exciting cause of mental disease.

CLINICAL MEMORANDUM.

A CASE OF MULTIPLE COSTAL RESECTION.[1]

BY A. STEWART LOBINGIER, M.D.,
OF DENVER, COL.;
PROFESSOR OF SURGERY IN THE MEDICAL DEPARTMENT OF THE UNIVERSITY OF COLORADO.

ON October 26, 1894, Mr. Wm. F., aged thirty-two, consulted me, upon the advice of Dr. W. B. Craig, for relief from an intrathoracic abscess. The pus from the empyema was discharging anteriorly through an oblique fistula. He had enjoyed good health up to 1892. Two and a half years previous to the time I saw him, he had had an attack of lobar pneumonia involving the left lung, which was accompanied by a severe pleurisy. The sero-fibrinous effusion which resulted had been so rigorously treated with erosive counter-irritants that the condition culminated in septic infection through the subcutaneous lymph channels. There had been no meddlesome interference with the exploring needle, cutaneous inoculation being the probable source of the infection. Thirteen months had been spent in treatment in Denver at the hands of several different physicians, and a diagnosis of phthisis pulmonalis had been made. He continued to grow worse in every way. His symptoms finally became so accentuated that death seemed imminent, and he determined to change from the climate and altitude of Denver to that of San Antonio, Texas. Upon reaching San Antonio, he consulted Dr. Van Koehring, who correctly diagnosed his case and gave him great relief by an intercostal incision, through which about two liters of pus escaped. No shock followed this operation, but he was given to understand that it ought to be followed by a resection of the ribs, and this, it was advised, should not be long delayed. The progress of the case from that date until several months later was so favorable that the patient deferred the radical operation. He gained so rapidly in appetite, weight, and strength that he and his friends considered further operative measures would be unnecessary. During the time subsequent to the pleurotomy the discharging sinus was dressed once a day by the patient himself with warm water and a covering of non-absorbent cotton.

In April, 1894, he returned to Denver, but as the abscess cavity became more profoundly infected, the symptoms of sepsis and failing vitality returned; so that at the time I saw him, six months later, his weight had fallen to 119 pounds, and he had a temperature of 101½° F. Cough was pronounced, and there was entire loss of appetite.

---

[1] Abstract of a paper read before the Denver and Arapahoe Medical Society.

On examination the right lung was found to be normal throughout. The left lung was densely consolidated at the base, posteriorly. There were moist râles in the upper area of the lower lobe, and infiltration and râles in the upper lobe. The heart was somewhat displaced to the right with the apex well into the subensiform depression. There was probably a quart of pus continually present in the abscess cavity, which discharged as best it might through an oblique fistula 1 inch internal to and 3 inches below the left nipple. A superficial exploration of the fistula was made to determine its direction. All further meddling was avoided. The patient was advised to undergo a multiple resection of the ribs as a radical remedy. He entered St. Joseph's Hospital, where, on November 1st, assisted by Drs. E. R. Axtell and J. B. Devlin, I performed a multiple resection, somewhat after the technic of Estlander. The patient had been prepared by tonic stimulants for several days, and eighteen hours' rest was given before the operation, during which strychnin and digitalis were exhibited in liberal doses.

After the usual disinfection and toilet on the table, a curved probe was passed to the lowest point in the cavity falling in the axillary line. By ventral pressure the impinging point of the probe became prominent through the thoracic wall, indicating the point of greatest dependency. At this point the intercostal incision and preliminary resection were made in order to permit of evacuation and washing out of the cavity previous to the general resection. After the resection of an inch and a half of the eighth rib, and enlarging of the seventh intercostal space for a similar extent, an attempt was made to wash out the cavity, but the cavity was so large, having a capacity of fully a liter and a half, and the walls were so resisting, that it was quite apparent that more than the legitimate time for the entire operation would be consumed in its antiseptic irrigation, and the opening was therefore plugged with antiseptic gauze and the general resection proceeded with. From a point 1 cm. above the fourth rib, opposite to the third intercostal space and 2 cm. posterior to the pectoral fold, I described the anterior line of an ellipse downward to the anterior edge of the primary exsection, carrying the knife through the skin, subcutaneous tissue and muscle. In a similar manner the posterior arc of the ellipse was described backward and downward, care being taken to lengthen the transverse axis in the descent so that the ellipse should present a somewhat pyramidal figure with its base downward, the incision ending at the dorsal angle of the opening into the thorax.

As rapidly as possible the elliptical flap and the portions of the latissimus dorsi and serratus muscles invaded were dissected up and the ribs exposed. The costal periosteum was incised laterally and the entire ventral portion stripped away, leaving the segment of the rib exposed and clean for immediate excision with the saw. All posssible speed consistent with careful work was exercised at this stage of the operation and segments of five ribs, of 1¾ to 4¾ inches in length, and embracing the fourth, fifth, sixth, seventh, and eighth, were excised. An additional segment of the eighth rib was removed, extending 1½ inches posterior to the primary exploratory exsection. The posterior half of the periosteal cortex of each rib was left intact, which, though an original modification of Estlander's method, was thought best in this case. In order to prevent possible infection, the upper portion of the wound was dried with sterilized sponges, and the edges down as far as the sixth intercostal space were brought together with retaining sutures of heavy silk. The edges of the severed latissimus dorsi and serratus muscles were included in these sutures. The exposed and unsutured area, from the seventh rib to the eighth interspace, was left exposed to heal by granulation. This surface, together with the line of sutures, was bathed with a 1–1000 bichlorid of mercury solution, and, as a further precaution against the possibility of the absorption of any septic material from the contents of the thorax, the area and line of sutures were packed with gauze moistened in the same solution, and the entire field protected as thoroughly as possible. The abscess cavity was now irrigated with a 1–1000 bichlorid solution. Two quarts of this solution were introduced, followed by the same quantity of a 1–2000 solution, and 4 quarts of salt solution. The temperature of the solutions was slightly above body heat.

The cavity, which had collapsed greatly after the excision and the application of the sutures, was yet sufficiently patent to allow of thorough irrigation of every portion. On exploring with a sound it was found that a dorsal counter incision to facilitate drainage was not indicated, and that the plane of drainage was upward and backward at an angle of 20 degrees. The cavity was packed with iodoform gauze, the wound sprinkled with iodoform, and the usual antiseptic external dressing applied. In the application of the roller, as tight constriction as was tolerable to the patient was employed at this and each subsequent dressing. At the third dressing it appeared from the small amount of packing which the cavity would receive, that coaptation of the walls had been general and symmetrical. This relation changed somewhat during the following three weeks, but the cavity steadily closed, although during the course of the irrigation and packing both pyrozone and balsam of Peru were used to hasten the formation of granulations.

The patient made a rapid and uninterrupted recovery, gained forty pounds in weight, and became muscular, ruddy, and able to do hard manual labor all day long. So jubilant was he over his return to health that he became reckless and intemperate, and after an exposure, seven months after he was discharged from my care, he was taken down with a lobular pneumonia, which was followed by a small effusion. On seeing him I learned that he had been hard at work for six months after I had last seen him, and had enjoyed the most robust health. His careless mode of life, however, had eventually reduced his resistance, and this variety of relapse resulted. The effusion, which was largely serous, was evacuated, the cavity carefully washed antiseptically, and the puncture sealed. The effusion did not return, and the patient, since this event, has been strong and hale. It is now over two years since he was operated upon, and a year since the occurrence of the second pneumonia with effusion, and he has remained perfectly well, with not a trace of disturbance of the operative area.

The heart, which had been so markedly displaced to the right, has swung back almost to its normal position. The upper lobe of the left lung and the upper fifth of the lower lobe are apparently patent and but slightly impaired, but the lower portion of the lower lobe is entirely gone. The depression from loss of tissue has been corrected to a great degree by the gradual regeneration of the thoracic wall. The curvature of the spine and consequent depression of the shoulder have been thereby corrected, and he stands as erect as one with an unimpaired thorax.

MEDICAL PROGRESS.

The Influence Exerted upon the Infant by the Physical and Mental State of the Wet-nurse.—BUDIN (*L'Obstétrique*, 1896, No. 4, p. 321) reports seven instances that illustrate the influence exerted by the state of the wet-nurse upon the infant at the breast. Three children nursed by a woman suffering from pain lost in weight. Two other children nursed by an angry woman also lost in weight; in both the bowels became loose. The same result followed when the woman undertook to nurse her own infant. Two children nursed by a menstruating woman lost in weight and developed an erythema of the thighs.

The Absorption of Albumins by the Rectum.—KOHLENBERGER (*Münch. Med. Woch.*, November 24, 1896,) carried out a long series of experiments in order to determine the amount of albumin which the rectum is capable of absorbing. As a result of his investigations he draws the following practical conclusions: Albumins introduced into the large intestine may be completely absorbed, and, if so, tend to nourish the individual. In this important particular they differ from those albumins that are injected directly into the blood, for these circulate in the organism as foreign material, and are eliminated by the kidneys without being used.

The Nature of Acute Articular Rheumatism.—LEREDDE (*Archives générales de Médecine*, August, 1896, p. 149) expresses the opinion that acute articular rheumatism presents characters that range it among diseases of microbic origin. The exciting cause is yet unknown; it may be a saprophyte, and is without doubt ærobic. It is to be looked for in the marrow of bone, in the blood or in the walls of the joints. It may possibly be found also in and about the pharynx, as anginas often appear to furnish a portal of entry. The disease belongs among the infectious arthritides of the serous variety which, like the purulent arthritides, are essentially blood-infections.

Acute Microbic Nephritis Secondary to a Wound of the Hand.—A case reported by PEDENKO (*La Presse Médicale*, December 19, 1896,) is of interest as demonstrating the possibility of a bacterial nephritis having its origin in the blood. The patient, a man aged twenty years, had a felon of the right middle finger, which was not opened until the suppuration had extended to the bone. Some days previously he had a general edema with dyspnea and headache and great weakness. Three weeks after the infection the urine was found to contain a staphylococcus albus, which was also found in the wound mixed with staphylococcus aureus and bacilli. The urine also contained albumin, blood, and casts. With the improvement of the wound the bacteria disappeared from the urine.

Addison's Disease Followed by Recovery.—CERVELLINI (*La Presse Médicale*, December 19, 1896,) was called upon to treat a man aged twenty-two, in whom, for a year, there had been increasing general debility with epigastric pain. The skin, especially of the hands and face, was brown, the liver was increased in size, the heart's action was irregular and there was loss of appetite, diarrhea and extreme weakness. The left testicle was tuberculous and much enlarged. There was no personal or family history bearing upon the case. A diagnosis of Addison's disease was made, but before commencing general treatment the testicle was removed. Ten days later all of the symptoms had improved except the intense epigastric pain. The patient was then put upon a strict nitrogenous diet and iodid of potash for two months, at the end of which time he was completely cured. He was afterwards seen by the author, and none of the symptoms had recurred.

ice. In the first place,

are destroyed and, therefore, less than the normal amount of bile secreted and, secondly, the constriction of the interlobular bile ducts is shared by the lymphatics in their immediate neighborhood. In hepatic cirrhosis, in short, the diseased sections of the liver are in the same circulatory conditions as is the entire liver in Harley's experiment.

In hypertrophic cirrhosis, the liver cells are not destroyed; bile is secreted abundantly, and there is obstruction to its outflow, occasioned by the constriction of the smaller bile ducts, for in this variety the hyperplasia of the connective tissue begins and continues as a periangiocholitis.

Exceptional cases undoubtedly occur in which jaundice accompanies atrophic cirrhosis, and such jaundice may be either of intra- or extrahepatic origin. For the production of the intrahepatic variety, it is only necessary that the compression exercised by the contracting connective tissue should impinge more powerfully upon the bile ducts than upon the lymphatics.

The commonest cause of extrahepatic jaundice, and one to which spirit drinkers, the most numerous victims of cirrhosis of the liver, are especially predisposed, is gastroduodenal catarrh.

apparently have caused death so soon had it not been for his marked lymphatic condition. The practical point of this experience is that children with the status lymphaticus, in spite of their splendid appearance, often sink raply under light attacks of the disease. The prognosis in such cases ought, therefore, to be guarded, the more so as such children are often looked upon by their parents as being particularly healthy. In these cases long continued hydropathic measures, narcosis, and, in brief, every kind of weakening therapeutic treatment ought to be avoided as far as possible.

Remarkable Hypothermia in a Case of Subacute Hepatitis of Toxic Origin.—At a recent meeting of the Société Médicale des Hôpitaux, Clarede (*Semaine Médicale*, 1896, No. 35, p. 276) reported the case of a man, twenty-five years old, presenting a state of great weakness, with coldness of the skin, cyanosis, small pulse and a temperature of 33.8° C. (92.8° F.). Under active therapeutic measures the temperature rose in the course of eight hours to 35.9° C. (96.6° F.), the asthenia, however, persisting. A day later the temperature had risen to 37° C. (98.6° F.). On inquiry it was learned that the patient had been exposed to the vapors of mineral acids. On further inspection the skin was found to be slightly icteric, while the urine was diminished in amount and contained albumin, urobilin and an excess of nitrogenous matters. The stools were decolored and glairy, and the liver was

ing out of the cavity previous to the general resection. After the resection of an inch and a half of the eighth rib, and enlarging of the seventh intercostal space for a similar extent, an attempt was made to wash out the cavity, but the cavity was so large, having a capacity of fully a liter and a half, and the walls were so resisting, that it was quite apparent that more than the legitimate time for the entire operation would be consumed in its antiseptic irrigation, and the opening was therefore plugged with antiseptic gauze and the general resection proceeded with. From a point 1 cm. above the fourth rib, opposite to the third intercostal space and 2 cm. posterior to the pectoral fold, I described the anterior line of an ellipse downward to the anterior edge of the primary exsection, carrying the knife through the skin, subcutaneous tissue and muscle. In a similar manner the posterior arc of the ellipse was described backward and downward, care being taken to lengthen the transverse axis in the descent so that the ellipse should present a somewhat pyramidal figure with its base downward, the incision ending at the dorsal angle of the opening into the thorax.

As rapidly as possible the elliptical flap and the portions of the latissimus dorsi and serratus muscles invaded were dissected up and the ribs exposed. The costal periosteum was incised laterally and the entire ventral portion stripped away, leaving the segment of the rib exposed and clean for immediate excision with the saw. All posssible speed consistent with careful work was exercised at this stage of the operation and segments of five ribs, of 1¾ to 4¾ inches in length, and embracing the fourth, fifth, sixth, seventh, and eighth, were excised. An additional segment of the eighth rib was removed, extending 1½ inches posterior to the primary exploratory exsection. The pos-

by cyanosis, with edema, accompanying paresis, paralysis or contracture of a part, and is attended by severe pain; acrocyanosis is free from edema, paresis, paralysis, or contracture and pain. Both Raynaud's disease and blue edema, as well as acrocyanosis, are of nervous origin, the last especially appearing to be an hysterical vasomotor phenomenon.

THERAPEUTIC NOTES.

Treatment of Copious Hematemesis.—Hirsch directs attention to profuse uncontrollable hemorrhage in ulcus ventriculi. As is well known, internal therapy, and rest and cold are useless in these cases. That instances of surgical interference are, as yet, few, is due to the fact that patients with gastric ulcer with profuse hematemesis are, as a rule, first placed in the medical wards and are seen by the surgeon only when it is too late. Hirsch, although recognizing the fact that the seat of the ulcer cannot always be located, yet favors operative interference even during a hemorrhage, following the maxim, "when blood squirts, ligate." Endoscopic examination of the walls of the stomach through the wound, just as in cystoscopy, he considers feasible in these cases. He concludes that operative interference is justified whenever (notwithstanding the most rigid rest and diet) there are repeated hemorrhages, which, by their frequency and profuseness, threaten the life of the patient. As an indispensable condition for operative interference, a certain diagnosis of hemorrhage *ex ulcere* must be established, eliminating hemorrhage due to cirrhosis of the liver, aneurism, atrophies, nutmeg liver and hemorrhages from the parenchyma of the stomach. The differential diagnosis between hemorrhage due to real ulcer and parenchymatous bleeding is not always easy to make.

Further Uses of Formaldehyd.—From Berlin (*Deutsch Med. Wochensch.* 1896, Nos. 39 and 40) comes the statement by Rosenberg that he has used formaldehyd in a new solution with gratifying results. The best known solution so far is a forty per cent. watery one known as formalin. Opperman used a sixty per cent. solution in methyl alcohol, which he called holzin. Rosenberg has experimented with the latter solution in combination with a small quantity of menthol to do away with its irritating properties. This fluid he calls holzinal, and when he allowed it to evaporate slowly from a small apparatus he obtained a perfect sterilization of the air and all objects in the room without injury. Even food was rendered absolutely free from germs by it. It had a favorable influence upon whooping-cough in all stages. When used in a solution as weak as 1–100,000 it prevents the development of bacteria, and a solution of a strength of 1–75,000 is germicidal. Formaldehyd was further given internally in a solution of milk sugar, (called sterisol). Examination of the urine shows that it is taken up by the blood, and is separated from it by the kidneys so slowly that its germicidal action in transit must be considerable.

THE MEDICAL NEWS.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

COMMUNICATIONS are invited from all parts of the world. Original articles contributed *exclusively* to THE MEDICAL NEWS will after publication be liberally paid for (accounts being rendered quarterly), or 250 reprints will be furnished in place of other remuneration. When necessary to elucidate the text, illustrations will be engraved from drawings or photographs furnished by the author. Manuscripts should be typewritten.

SPLENIC ENLARGEMENT AND JAUNDICE IN CIRRHOSIS OF THE LIVER.

TUMEFACTION of the spleen is commonly described in medical text-books as a necessary consequence of cirrhosis of the liver, and is invariably attributed to interference with the return of blood through the splenic vein. That this is a contributing cause to such tumefaction there can be no doubt, but that it is not the sole cause was pointed out by Senator in 1893 (*Berlin. klin. Wochenschr.*, No. 51, 1893). This well-known authority calls attention to the fact that, while the obstruction to the portal current is most marked in the radicles of the mesenteric veins, swelling of the spleen is an early manifestation of cirrhosis, and sometimes persists when all other signs of portal obstruction have subsided.

Again, swelling of the spleen is observed in cases of the hypertrophic cirrhosis of Hanot, in which signs of portal obstruction, more particularly ascites, are absent. In fact, enlargement of the spleen is relied upon by Senator as a differential point of diagnosis between hypertrophic cirrhosis and catarrhal jaundice. The early appearance of the splenic enlargement is especially important in this respect, because hypertrophic cirrhosis, in its beginning, is very apt to be confounded with catarrhal jaundice.

So far, then, from corroborating the commonly accepted doctrine that tumefaction of the spleen, coinciding with hepatic cirrhosis, is due solely to portal congestion, the facts speak rather in favor of some direct splenic irritant, such as alcohol, syphilis, malaria, or possibly microbic infection. In other words, the causes of the splenic swelling are probably, in part, the same as give rise to the various forms of hepatic cirrhosis.

The presence or absence of icterus in cases of cirrhosis of the liver depends both upon the activity of the hepatic cells and the condition of the bile ducts. Unless bile is formed it cannot be absorbed, but mere obstruction to the outflow of bile does not necessarily give rise to jaundice. In addition, it is indispensable that there be free communication between the lymphatics of the liver and the blood current. As was pointed out by Vaughan Harley, simultaneous ligature of the common bile duct and the thoracic duct is not followed by jaundice.

The conditions of Laennec's cirrhosis (atrophic cirrhosis) are unfavorable to the production of jaundice. In the first place, many of the hepatic cells are destroyed and, therefore, less than the normal amount of bile secreted and, secondly, the constriction of the interlobular bile ducts is shared by the lymphatics in their immediate neighborhood. In hepatic cirrhosis, in short, the diseased sections of the liver are in the same circulatory conditions as is the entire liver in Harley's experiment.

In hypertrophic cirrhosis, the liver cells are not destroyed; bile is secreted abundantly, and there is obstruction to its outflow, occasioned by the constriction of the smaller bile ducts, for in this variety the hyperplasia of the connective tissue begins and continues as a periangiocholitis.

Exceptional cases undoubtedly occur in which jaundice accompanies atrophic cirrhosis, and such jaundice may be either of intra- or extrahepatic origin. For the production of the intrahepatic variety, it is only necessary that the compression exercised by the contracting connective tissue should impinge more powerfully upon the bile ducts than upon the lymphatics.

The commonest cause of extrahepatic jaundice, and one to which spirit drinkers, the most numerous victims of cirrhosis of the liver, are especially predisposed, is gastroduodenal catarrh.

THE CORSET HABIT.

NOTHING is more extraordinary than the attitude of the profession at large upon the above-mentioned subject. Even the position of the corset wearer herself is less astonishing, for we have of course long ago ceased to be surprised at *anything* which lovely woman may choose to do or not do. She will or she will not—usually the latter—and we have learned to ejaculate a perplexed but submissive "Kismet," and accept the situation. Beyond the awful fact of her decision, the coarse intellect of man seeks in vain to penetrate. But from our fellow males we arrogate the right to demand those clumsy and labored excuses for one's attitude which we politely dignify by the name of "reasons." In this case they will be even harder to find than usual.

For over a century the leaders of our profession have been thundering against the corset and all its works. Every new investigation has added another to the long list of deformities produced by it. Absolutely nothing can be urged in its favor or even extenuation. It is established that the pressure of the corset seriously interferes with respiration and deforms the chest, displaces and distorts the liver, even to the extent of burying the lower ribs in grooves upon its surface, forces the stomach and intestines downward to press upon the uterus, thus producing versions and displacements, dislocates the kidney and plays general havoc with any and all of the viscera, thoracic, abdominal, and pelvic. That this instrument of torture is both capable and often guilty of all these offenses any intelligent physician knows both from unquestioned authority and by experience, and yet most of us are saying little and doing less to effectually discourage its use. We seem ready to ejaculate in weary despair what Tweed did in insolent defiance, "What are you going to do about it?"

We all know from experience the reason for this discouragement, the polite and pitying smile of half incredulity, half indifference with which our most earnest protests are met. "Oh, of course, its my corset! you doctors always blame that. I don't believe it for a minute—but anyway I couldn't live without it!" The unwritten laws of fashion may be as silk to the eye, but they are steel to the touch, and we are compelled ruefully to acknowledge that in an even deeper sense than that probably intended by the poet "there is no use disputing about matters of taste." Still we should remember that it was not until the seventh blast of the ram's horns after the tenth circuit of the city that the walls of Jericho fell down and nerve ourselves for another blast against the even higher (and much thicker) ramparts of Mrs. Grundy's prejudice and stupidity.

And this is the more incumbent upon us since every new development of late years so far from causing us to regard the corset habit in a more indulgent light, supplies fresh proof of its harmful nature and logically demands an even more unsparing denunciation and antagonism to it. Those who know most of it condemn it most severely. The gynecologists are almost a unit against it. In his late presidential address before the American Gynecological Society, Mann declares that the profession has not taken "sufficiently strong ground on this very important matter," and that "displacements, not only of the uterus but of all the abdominal viscera may result from only moderate waist constriction." This displacement not only is a source of injury in itself, as in floating kidney and in tension upon the solar plexus, but, by destroying the tone of the muscular coat of the stomach and intestines, favors food stasis with its resultant constipation and intestinal taxemia on the one hand, and on the other lithemia with all the Pandora's box of evils which follow in its train. In his opinion no small proportion of all the "diseases of women" are due to the lithemia and toxemia thus produced; and the frequency with which these displacements actually occur may be estimated by the fact that he has found the transverse colon below the umbilicus in more than fifty per cent. of his ovariotomy cases. Still more recently Kelly has again demanded the attention of the profession to the enormous amount of "ill-health, neurasthenia, and displacements of the kidneys and pelvic organs which come from the corset habit."

But these fresh arraignments are pressed home most vigorously from a somewhat unexpected quarter. For some years past those investigators who have devoted themselves specially to the diseases of the stomach have been coming to the conclusion that downwarn displacements of the viscera under the somewhat appalling titles of *gastroptosis* and *enteroptosis* are among the most common and potent causes of chronic digestive disturbances. For some time it was doubted whether this was a cause or an effect of the gastric and enteric disturbances of function, but further observations soon decided beyond question that in the great majority of cases not only was the gastroptosis the original cause, but that no adequate or lasting relief of the functional disturbances could be afforded until the "prolapse" was remedied or lessened. The question then arose whether the primary fault lay in elongation and weakening of the mesenteries, or in lack of adequate support to the intestines by the abdominal walls, and it was found that any influences which produced lack of tone in the recti and oblique muscles might give rise to this condition. This of course at once explained the hitherto puzzling fact that these ptoses were nearly six times as frequent in women as in men. Glenard of Lyons first called attention to this in 1885; his statements have since been confirmed by no less authorities than Ewald and Einhorn, with a number of lesser lights, and all agree in ascribing the almost sole responsibility for this state of affairs to the corset habit and its associated idiocies.

ECHOES AND NEWS.

American Medical Association.—The members who desire to read papers before the Section on Neurology and Medical Jurisprudence are requested to notify the secretary, Dr. C. H. Hughes, 3857 Olliver street, St. Louis, Mo.

Ravages of the Plague.—The returns of the health authorities, Bombay, February 18th, showing the ravages of the plague, report that since its outbreak there have been 6853 cases and 5447 deaths in the city, and in the entire Bombay Presidency 9911 cases and 8006 deaths.

The Woman's Medical College of New York.—This institution is making a strong appeal for financial assistance. It is said by its officers that it has reached a point where it is in serious danger of being destroyed by its own growth. An effort is being made to raise a fund of at least $200,000 as the only means of placing the institution on a secure foundation.

The Optometry Bill in the New York Legislature.—Despite the fact that a strong representative committee of doctors from Albany and New York appeared before the Assembly committee and opposed the provisions of the bill, it was reported favorably and ordered to a second reading. An effort is being made to induce the friends of the bill to allow it to remain indefinitely upon the table.

To Keep Healthy.—The following dietary is recommended: Eat fruit for breakfast and for luncheon. Avoid pastry. Shun muffins and crumpets and buttered toast. Eat whole-meal bread. Decline potatoes if they are served more than once a day. Do not drink tea or coffee. Walk four miles every day. Take a bath every day. Wash the face every night in warm water and sleep eight hours.

Roosevelt Hospital Alumni Association.—The monthly meeting of Roosevelt Hospital Alumni was held at the Hospital on the 19th of this month. Some interesting cases were shown by Dr. Homer Gibney and pathological specimens by Dr. LeBoutillier. The paper of the evening by Dr. Geo. Woolsey was upon "Massage in the Treatment of Fractures," giving the views of French and German authorities.

A Lawyer's Fee for a Doctor's Work.—It is reported that the House Surgeon of St. Catherine's Hospital, Williamsburgh, N. Y., charged the widow of a patient who had died in the hospital $25 for filling out and signing a certificate to enable her to obtain the insurance on her husband's life. The amount of the insurance was $1500. The executive committee of the hospital has been asked to investigate the matter.

The Legal Powers of Health Officers.—During a recent epidemic of smallpox in Brooklyn, Health Officer Emery sent an inspector to vaccinate a man and his family. The head of the house ordered the doctor out, whereupon the latter placed a policeman at the door and kept the family prisoners during the entire day. Suit for damages was brought against the health officer and judgment was secured placing damages at $489. An appeal was taken and is now being argued before the Supreme Court.

Tuberculous Meat Sold.—A wholesale dealer in meats has been arrested in Portland, Me., on a charge of selling beef diseased with tuberculosis. He bought a herd of cattle which had been ordered killed by the Cattle Commissioners, being badly afflicted with tuberculosis. The sale was made with the consent of the Cattle Commissioners, with the understanding that the purchaser would take the cattle to his rendering factory and try out their carcasses for grease. It is alleged that he dressed them for food, and that at least ten carcasses were brought to Portland, where they were sold to customers all over the city for food.

A Doctor Dies of the Plague.—In the beginning of January, Dr. Manser, President of the Sanitary Commission at Bombay and professor of the faculty of medicine, became ill. It was reported that he had inflammation of the lungs, but four days afterward he died, and the European hospital nurse who attended him died three days after him. The death of Dr. Manser caused profound excitement, especially when it was reported that in his blood and in that of the hospital nurse the presence of the bacilli of the plague was detected. It is now certain that the plague finds an easy lodgment in the organs of respiration when they are affected with colds or other troubles.

Insanity and Idiocy Increasing in Kansas.—It is reported that despite the decrease in population insanity is on the increase in the State of Kansas. In 1890 the two State insane asylums had 1127 patients; to-day there are 1736, or an increase in the State's insane of more than forty-one per cent., with a decrease of more than six per cent. in population. These figures do not include all those who have legally been declared to be of unsound mind. A dozen counties now have bills against the State for taking care of insane people who could not be admitted to the asylums. Authorities on the subject say that the increase is largely due to the financial stringency, worry, and discontent prevalent in the State.

Obituary.—Dr. Henry Creamer, one of the leading physicians of Williamsburg, Brooklyn, died suddenly of pneumonia at his home February 20th. He came from a family of physicians who were prominent in the Eastern District of Brooklyn. His father, grandfather, and brother were coroners of Brooklyn. Dr. Creamer was only twenty-eight years old. Dr. Saturnino M. Jiménez died February 17th at his home, 16 West Eighty-fourth street, New York, of pneumonia. He was born in Matanzas, Cuba, in 1851. His father was Antonio Jiménez, an extensive planter, who became impoverished through the ten years' war. Dr. Jiménez graduated from Jefferson Medical College, Philadelphia, in 1878, and came to New York in 1882. He leaves a wife and two children.

Extraordinary Contents of a Woman's Stomach. — Dr. Fricker of Odessa, reports an unusual case of foreign bodies in the stomach. The patient was an insane woman, thirty-two years of age, who presented herself with an apparent abscess in the left side of the abdomen. Upon opening the abscess it was found to communicate with the stomach. With all due precautions the stomach was opened, and the following bodies removed: A key, a silver teaspoon, a metal teaspoon, a fork, two wire tacks, two hairpins, two pieces of glass, one window hook, one steel pin, nine sewing needles, one piece of black lead, one shoe button, one grape stone, two small lumps of tin, and one crochet hook. The stomach was washed out with sterilized salt solution and the wound closed. The patient made a good recovery.

The Best Artificial Light.—Professor Crookes has called attention to the fact that the best form of artificial light is one containing little or no ultra-violet rays, no excess of yellow rays, and just sufficient red light to communicate a warm, pleasant tone to objects around; that light which is more than normally rich in violet and ultra-violet rays is injurious to the eyes, contributing in time to a partial destruction of the fibers of the crystalline lens, and, when excessive, producing erythema and symptoms resembling those of sunstroke—workmen in electric light works, if frequently exposed to powerful arc lights, being affected in this way. It is not desirable, however, that the light should be too rich in yellow rays, as these temporarily destroy the erythrosin or photo-sensitive substance of the retina, producing great fatigue of the nerve.

The Serum Treatment of the Plague.—All the reports from India unite in recognizing the value of the serum treatment as a means of limiting or putting an end to the bubonic plague. Just as in diphtheria, and as must be the case if the antidote is really efficacious, the cure has been most rapid when the treatment has been applied on the first day of the disease; speedy, also, but less so, when it began on the second day, and so from day to day till the fifth. Four patients have been treated at this very late period, and the only failures were in two of these. More of the serum is required in the more advanced cases. Equally striking is the manner of recovery. In twelve cases in which treatment began within two days of the onset of the complaint, the patients instead of having a lingering convalescence, were healthy men and women in a time which was always relatively short. Lord Lister, in his recent address at Belfast, says: "These details are so extraordinarily confirmatory that, small though the number of cases is, they carry conviction to my own mind."

The Horrors of the Plague.—The *Independent Belge* gives the following picture of the condition in Bombay: "The government does all it possibly can to allay the panic. Camps and tents have been set up in the public places to shelter those who have fled from houses in which the plague appeared. The salaries of the employees in the municipality were doubled, but without success. The officials fled. It is difficult to diminish the terror of the natives. Lectures, encouragement, and advice in regard to hygiene have all been worthless. It is impossible to reason with terror; and, as a matter of fact, it is necessary to have a stout heart to be able to resist the contagion of fear, when, from morning till evening, there is one continuous procession of funerals; and in the evening the sky is reddened with the fires that consume the bodies. An absolutely terrifying spectacle is presented at the Queen's road square where the Hindoos burn their dead. At a considerable distance we can see the huge columns of smoke and hear the wails of the relatives, the lugubrious sound of the cymbals, and the cracking of the blazing wood. The government employs learned doctors, who hold conferences, debate, and make propositions; but the medicines that are distributed have no effect upon the plague. The houses are whitewashed, odoriferous plants are burned in the interior, the clothes and furniture in the houses where there were deaths from the plague are also burned, and even the tiles on the roofs have been taken away for the purposes of ventilation. But all seems in vain.

The American Laryngological, Rhinological, and Otological Society.—The Southern Section of this Society will hold its next meeting in New Orleans, La., March 3, 1897, at the new St. Charles Hotel. In addition to numerous social functions the following program is announced: "Operative Treatment of Suppurative and Non-Suppurative Middle Ear Inflammations," Dr. E. B. Dench, New York; "Remarks upon Tonsil Operations with especial reference to Hemorrhage," Dr. A. W. Calhoun, Atlanta, Ga.; "Surgery of the Inferior and Middle Turbinated Bodies and Bones," Dr. Robt. C. Myles, New York; "Some Amusing Instances of Nasal Reflex," Dr. Arthur G. Hobbs, Atlanta, Ga.; clinical report of interesting cases: (1) "Two Cases of Tracheotomy for Foreign Body in the Trachea;" (2) "Cicatricial Atresia of Both Choanæ," Dr. Augustus McShane, New Orleans, La.; "The Classification and Nomenclature of Acute

Diseases of the Tonsils," Dr. T. C. Evans, Louisville, Ky.; "Sero-Mucous Cysts of the Alæ of the Nose." Dr. Norval H. Pierce, Chicago, Ill.; "Relation between Nasal and Mental Diseases," Dr. D. Ziem, Dantzig, Germany; "Turbinectomy: Analysis of One Hundred Cases," Dr. J. A. Stucky, Louisville, Ky.; "The Necessity of the Complete Removal of the Tonsils whenever Diseased or Hypertrophied," Dr. Louis J. Lautenbach, Philadelphia; "Spurs of the Nasal Septum as Factors in Diseases of the Respiratory Tract," Dr. Edward F. Parker, Charleston, S. C.; "Treatment and Prognosis of Catarrhal Deafness in Young Children," Dr. J. Aloysius Mullen, Houston, Tex.; "The treatment of Laryngeal Tuberculosis with Cupric Interstitial Cataphoresis, with the Report of Cases; The Advantages of Direct Laryngoscopy in this Method," Dr. W. Scheppegrell, New Orleans, La. Exhibition of new instruments. Session at 7 P.M. at the reception room of the French Opera House. Address by Judge A. G. Brice, Chairman Auxiliary Reception Committee, "The Division of Labor and the Development of Specialism."

CORRESPONDENCE.

LARGE DOSES OF ANTITOXIN IN DIPHTHERIA.

To the Editor of THE MEDICAL NEWS.

DEAR SIR: The following is the fortieth case of diphtheria treated with antitoxin by the writer, and is reported because of the large amount used. Of the forty cases four were fatal. Three patients, it is believed, would have lived could the injections have been given earlier. One died ten days after supposed recovery; cause not known. The routine treatment was calomel, strychnin, saturated solution of menthol in fat applied over neck and chest, and local applications, if possible, in the tonsillar and pharyngeal cases, of Löffler's solution.

Injections were never less than 1000 units, except in two cases for prophylaxis where there was strong suspicion of beginning disease and 500 and 800 units each were used. Three cases—one fatal and two recoveries—had 3000 units each; four, all recoveries, 1500 units each.

Nearly all the patients were children from three to eight years of age. There was one adult, and one baby, ten months old. The baby was given 1000 units, and dyspnea grew so severe that six hours afterward death seemed certain. Three hours later she was found sleeping quietly.

No bacteriological examinations were made, but as an unknown number of children died during the epidemic without medical care and parents waited until they could themselves see grave symptoms before calling a physician, it is felt that the clinical diagnoses were correct. Dr. J. T. Pickerill saw the following case with the writer, and agreed in the diagnosis: January 3, 1897, 4 P.M. Pearl M., aged four years. Day of illness not known. Marked pallor, glands of neck swollen; harsh breathing, croupy cough; membrane over tonsils, which were badly swollen, covered as much of pharynx as could be exposed. Temperature, 100½° F.; pulse, 120; respiration, 24. One thousand units of antitoxin was given and at 9 P.M. 800 more, as stenosis was marked.

January 4th the membrane showed a bright red border and was beginning to clear from tonsils, but respiration was extremely labored and at 11 A.M. 1000 additional units of the antitoxin were given. As before, in six to eight hours, respiration was easier for a time and then grew worse.

January 5th it was thought that a new patch of membrane was forming on the left tonsil, and at noon 1500 units of antitoxin was injected, making 4300 in all. Between 2 and 3 P.M. the child relaxed and cuddled over in her pillow, the first time in forty-three hours. Later, forced respiration gradually ceased, and at 9 P.M. she slept quietly.

There were never any unpleasant symptoms from the serum, and recovery was uneventful. The membrane disappeared from the throat January 11th. There was no albuminuria and has been no paralysis.

Very truly yours,
ELLA CAMP, M.D.

LEMONT, ILL.,
February 3, 1897.

OUR PHILADELPHIA LETTER.

[From our Special Correspondent.]

GYNECOLOGICAL SECTION OF THE COLLEGE OF PHYSICIANS—REPORTS OF THREE RECENT CÆSARIAN SECTIONS—CURIOUS CASE OF SEPTIC SALPINGITIS—DR. J. CHALMERS DA COSTA ELECTED CLINICAL PROFESSOR OF SURGERY AT JEFFERSON MEDICAL COLLEGE—A NEW HOSPITAL FOR DISEASES OF THE STOMACH—DR. WILLIAM OSLER ON "THE INFLUENCE OF LOUIS IN THE STUDY OF MEDICINE."

PHILADELPHIA, February 20, 1897.

AT a meeting of the Gynecological Section of the College of Physicians held on Thursday, February 18th, Dr. Barton Cooke Hirst read a paper on "The Operative Treatment of Prolapse of the Ovary." He also reported two recent Cæsarian sections. The patients, both rachitic dwarfs, had made uninterrupted recoveries and with their children had already left the hospital, in good condition. A septic salpingitis of curious origin was also reported by Dr. Hirst. The patient was delivered about two years ago of twins. After the birth of the second child the woman declared, despite the assurance of the attending practitioner to the contrary, that there was another child. A few days later a third child was expelled in almost gangrenous condition with the subsequent septic condition of the tube. In the discussion incident to the subjects presented by Dr. Hirst, Dr. Richard C. Norris reported a case of Cæsarian section that he had recently performed. The patient had been in labor two days without any advance having been made because of a large fibroid tumor, which obstructed delivery. As soon as the doctor saw the case in consultation he decided on the operation mentioned, which was done at once. The patient, however, was already thoroughly septic and succumbed to the effects of that condition.

The election this week of Dr. J. Chalmers Da Costa to the position of Professor of Clinical Surgery at Jefferson

Medical College is a source of much satisfaction to the student body and friends of the institution. Dr. Da Costa has for years acceptably filled the posts of Demonstrator of Surgery and Chief of the Outpatient Surgical Department at Jefferson College. He is a fluent and forceful speaker and writer, a thorough teacher and a skillful operator.

The annual address before the Stillé Medical Society of the University of Pennsylvania was delivered on February 16th by Dr. William Osler of Johns Hopkins University. He had for his subject "The Influence of Louis on the Study of Medicine." Reviewing the life work of this eminent French savant he mentioned a number of his original theoretical conceptions as to the treatment of disease which have since crystallized into practical application.

Within a short time an institution to be known as The American Hospital for Diseases of the Stomach will be established in this city. The building will be located at the corner of Brown and Broad streets, and contain over fifty rooms adapted for use as wards, laboratories, and operating rooms. The objects of the hospital will be to treat all diseases of the alimentary tract, to establish a laboratory for original research, and to institute a school of dietetics.

The Board of Managers comprises some of the most influential men in the city, while the medical staff will be made up as follows: Dr. J. M. Da Costa, Dr. William Osler, Dr. W. W. Keen, Dr. James Tyson, Dr. John B. Denver, Dr. D. D. Stewart, Dr. Lewis Brinton, and Dr. E. K. Perrine.

OUR PARIS LETTER.

[From our Special Correspondent.]

THYROID GLAND IN THE TREATMENT OF EXOPHTHALMIC GOITER—CADOT'S METHOD OF CURING HUMPBACKS—YERSIN'S WORK IN CONNECTION WITH THE BUBONIC PLAGUE—THE TOXICITY OF THE URINE OF EPILEPTICS.

PARIS, January 30, 1897.

PROFESSOR FELIX VOISIN exhibited at the Academy of Medicine some time ago two patients suffering from exophthalmic goiter in whom there had been such amelioration of symptoms as to practically amount to a cure. A little later he reported two additional cases, and at a lecture at the Salpetriere last week showed a fifth case, and announced that the condition of the other reported patients remained entirely satisfactory. The only treatment employed has been the ingestion of thyroid gland, which goes to show how beautifully varied are the results of clinical therapeutics when only in the empiric stage. As the result of Owens', of Manchester, report some years ago, of improvement in Grave's disease after thyroid feeding, everyone who had a case under treatment, and a few others beside, made a trial of it. The results were, to say the least, not encouraging, but rather the opposite, so much so, in fact, that the theory was rather generally adopted that the symptoms of Grave's disease were due to overwork on the part of the thyroid, an excessive secretion of its peculiar and important principles, their accumulation in the blood and a consequent thyroid intoxication. Then for a time there was a good chance for the hypercritical to talk about the folly of "mortals rushing in where angels scarce dare to tread" and "prescribing tissue products of which they knew absolutely nothing for diseases of which they knew less." There are a number of those stereotyped expressions that make forcible writing rather easy for the obdurate critics of the poor individuals who are trying to broaden the field of therapeutics.

Then came Owens' ingenuous confession that he had been mistaken in reporting successes with thyroid medication since, through a mistake of the butcher to whom he applied for the material, it was not thyroid but thymus gland that his patients had been taking. Meantime, with the generally accepted theory of the etiology of the disease, due to the exaggerated symptoms attendant upon the thyroid treatment, that is, that the symptoms were due to an intoxication secondary to thyroid hypersecretion, a scheme of serum-therapy was evolved.

Animals were deprived of their thyroids, and after the symptoms of thyroidism (or dethyroidism) had began to show themselves, *i.e.*, at a time when the serum was supposedly totally wanting in thyroid material, it was injected into patients presumably suffering from hyperthyroidism with the idea of diluting the morbid products present, and leading to their more easy elimination. Theoretically, this serum-therapy seemed not unpromising, although the reports of any notable successes are yet wanting. Now comes another important element in the matter, and it would seem that many of our only recently acquired notions of the physiological functions of the thyroid must be changed once more. About a year ago Gley reported to the Society of Biology that the removal of the thyroid gland of animals did not produce the symptoms of myxedema usually attributed to such action. His report was confirmed later by the work of Rouxeau who had carefully removed the thyroids of sixty-five animals, but just as carefully respected their parathyroid glands—a name he gives to certain little glandular bodies, usually four in number, lying close along the thyroid—the operations always being followed by negative results as regards what has been called thyroidism, or myxedema. He now reports 105 cases in all of operations on the thyroid and parathyroid, and concludes that it is these latter hitherto neglected bodies that play the important etiological rôle in the accidents of myxedema. The conclusion is meeting with a great deal of opposition in Germany I believe, though there are some confirmatory observations from every country in Europe, but here in France at a recent session of the Society of Biology, the great opponent of the new doctrine acknowledged his submission and even reported as the result of his personal experiences that the seriousness and extent of the acute constitutional symptoms that were set up in a given case depended on the number of parathyroids removed. The removal of one had very little effect, except the production of a compensatory hypertrophy on the part of the others. The removal of two occasioned noticeable though not very grave myxedemic symptoms. When all were removed, though the thyroid was carefully respected, serious myxedema was the inevitable result.

And there, for the present, the matter rests. Only that the pleasure of hunting is in the chase not the capture, one would almost wish to lift the veil of life for the next twenty-five years and come at once upon the solutions of so many important questions in so many lines in medicine that are vexing scientific medical minds at present.

A recent report of a series of observations of the blood in myxedema, made at Bicêtre, seems to show that there are certain rather easily noticeable changes in the red blood cells. These are larger than usual and often have nuclei. Their number varies in different cases, but the variation does not seem to be a function of the disease, and bears no special ratio to its intensity. There is no leucocytosis and no noticeable change in the white blood cells. The hemoglobin is always lowered, even proportionately to the number of red blood cells when that number is considerably below the normal.

In reporting the last French Surgical Congress in October I mentioned Chepault's method of correcting to some extent and preventing the further progress of the curvature of Pott's disease by what the inventor calls apophyseal ligature. The French newspapers (what they call the political press) recently have had a number of articles on Dr. Cadot's method of curing humpback. Some of his patients were presented at the Academy of Medicine a short time ago. The method consists in forcible correction of the deformity and the retention of the spinal column in a straight position by a carefully applied Sayre jacket. It is applicable, especially it would seem, to recent cases, where the deformity is just beginning to be noticeable, and some of the results obtained seemed to have been very good. Just what it will amount to it is hard to say as its exaggerated exploitation by the non-medical press has surrounded it just now with something of a visionary air. It would seem clear, however, from results obtained by these two methods that the spinal column will, even in cases of tuberculous caries, put up with much more interference than orthopedists generally have been ready to acknowledge.

At the Academy of Medicine on January 26th, Roux read an account of Yersin's work in the treatment of the bubonic plague in Annam with serum provided by the Pasteur Institute here in Paris. Yersin, whose work with Roux on toxins, especially of diphtheria, will be remembered, was sent by the French Government to its colonies in Cochin China, for the purpose of instituting methods of combating the dreaded plague. The story, as told in a series of letters to his confrère in Paris, reads like the accounts of the old missionaries to the heathen. There was the same distrust on the part of the natives of the meddlesome foreigner, and the same objection to be the first to try the new remedy, the finding of a suitable case and opportunity at length, and then the flocking around him of so many importunate friends and relatives demanding his attention for their sick ones at all hours of the night and day, that with his stock of serum exhausted, Yersin had to leave the neighborhood where the cures had been effected.

The results obtained with the serum were very gratifying to the director of the Pasteur Institute. Twenty-six cases were treated with but two deaths, and these occurred in patients who were practically moribund when the injections were made. It is to be hoped that the much dreaded plague is to be wiped out at last as well for the sake of the poor, suffering natives as for the fact that Europe will be saved paroxysmal spasms of dread of its becoming epidemic here in the West. Occasionally, during these past few weeks there have been, according to the newspapers, some cases of bubonic plague in Paris, but this has always been denied by the health authorities.

Commerce with India is being watched very closely and the reshipment of some goods at London that had come from India and were put aboard a vessel that was to come all the way up the Seine, aroused a storm of newspaper indignation. The goods had been shipped from India, however, long before the plague broke out, a fact that perhaps the reporter of the fact originally knew very well, but the story was too good a one not to be written up.

Voisin's report of some two years ago as to the hypotoxicity of the urine of epileptic patients almost constantly, but especially just after an attack, is now confirmed by the careful report of M. Mairet, made to the Academy of Medicine also on January 26th. M. Mairet claims that this lowered urinary toxicity will enable one to detect simulation, to differentiate from hysteria, and to study with assurance the larval forms of epilepsy. Voisin's work did not attract very much attention. Anyone who has seen series of urinary injections made into animals while at the same time corresponding amounts of physiological salt solution are injected, knows how extremely unsatisfactory are conclusions founded on the reactions in the animal organism.

Vienna.

DECIDUOMA MALIGNUM OCCURRING DURING PREGNANCY—PIGMENTED HAIRY NEVUS CURED BY THE ROENTGEN RAY—CAUSES OF MUSHROOM POISONING.

AT the session of the Imperio-Royal Society of Physicians held January 15, NEUMANN described a case of *deciduoma malignum occurring during pregnancy* in a woman aged forty. The diagnosis was made from the local metastases occurring in the vagina. The uterus was at once curetted, and at the expiration of the puerperal period hysterectomy was performed. Neumann called attention to the necessity of frequently examining a woman in whom an hydatid mole has grown, both during pregnancy and after labor, because such a mole can very easily terminate in a malignant growth.

FRUEND reported a case of *pigmented nevus in a child treated by the Röntgen ray*. The nevus covered a portion of the neck and back and extended upon the sides of the thorax and upper arm. Portions of it were thickly covered with hair. When the treatment, which lasted two hours daily. had been carried out for eleven days the hair began to fall out, and in a short time there was a total alopecia of those portions of the nevus which had been exposed to the cathode rays. An accompanying dermatitis healed quickly under ichthyol salve, leaving the surface absolutely free from hair. Another portion of the nevus, which had been exposed to the anode rays, showed no change whatsoever. The effect of the rays was evident as early as the seventh day. It is a cumulative effect, as was shown by its continuance after the rays were discontinued. Six weeks after the beginning of the treatment there was no evidence of the return of the hair.

Semann who made the microscopic examinations in this case found an atrophy of the hair roots, the sections presenting appearances similar to those seen in alopecia areata.

Weiss discussed the subject of *mushroom poisoning* before the Medical Club January 20, 1897. Investigations have proved that mushrooms contain as high as twenty per cent. of proteid material, but that two-thirds of this passes away undigested, so that from a nutritive standpoint, mushrooms rank with other vegetables. The poisonous qualities of mushrooms may be due not only to the species, but also to the conditions under which they have been kept, and to the method of preparation. Harmless mushrooms, for instance, if gathered and kept moist may become poisonous. The most important active principle of one of the commonest of the poisonous mushrooms is muscarin. This alkaloid increases the activity of the glands and produces weakness of the heart, dizziness, ringing the ears, and death by respiratory failure. As an antidote very small doses of atropin have been recommended. In the selection of mushrooms for food those should be rejected which have become dry, as well as those which have been gathered and kept very moist.

Paris.

TREATMENT OF PLAGUE BY ANTIPESTOUS SERUM CAUSE AND PREVENTION OF BILIOUS VOMITING AFTER GASTRO-ENTEROSTOMY—A NEW METHOD OF DIAGNOSIS IN TUMORS OF THE LIVER—THE EFFECT OF COAL DUST IN THE LUNGS.

Before the Academy of Medicine January 26th, Roux read a communication from Yersin under whose direction *twenty-six cases of plague at Canton and Amoy were treated with an antipestous serum* obtained from a horse after numerous injections of plague bacilli into its veins. Three weeks after immunity was established in the animal the serum was tried on mice and found to exert a preventive action. It was then tried upon human patients. The whole number of persons suffering from the plague who were treated by this method was twenty-six. Only two of these died, both of whom received the inoculation on the fifth day. The mortality was therefore 7.6 per cent. Another proof of the efficacy of the serum treatment is the rapid recovery of the patients, whereas, ordinarily, convalescence is long and tedious even in benign cases.

Hayem read a report February 2d upon the *disintoxication of the blood.* The basis for the report was a series of cases treated by Barré. The treatment consisted in the withdrawal from one arm of the patient of a certain quantity of blood, while at the same time the same quantity of salt solution was injected into the other arm. This treatment was employed in one case of pneumonia, one of cerebral rheumatism, and two of uremia. In every instance there was a rapid recovery. Hayem called attention to the fact that these cases were of a character to be benefited by blood letting alone, so that further proof is needed before accepting Barré's conclusions as to the special merits of this method of treatment.

At the session of the Surgical Society held January 20th, Reynier discussed the *ill-effects of gastro-enterostomy and the means of preventing them* He cited instances in which patients have been seized with continuous bilious vomiting, the cause for which could not be ascertained. He thought that such vomiting may be due to a kink in the intestine where it joins the stomach. Such a condition he found once at autopsy, and on account of this kink, all the contents of the stomach were pushed back into the upper end of the duodenum, nothing passing into the lower end which was completely flattened.

This difficulty has been pointed out by a number of surgeons, and Woelfler advised twisting the loop of the intestine before suturing it to the stomach, so as to permit the gastric contents to pass freely into the lower part of the duodenum.

Quenu said that he had performed gastro-enterostomy a number of times, and that although he had never twisted the intestinal loop, he had never seen any kinking.

Chaput had observed continuous vomiting in two cases, the cause of which at autopsy was found to be an unusually short mesentery, and the selection of a point in the intestine for anastomosis too close to the pylorus. He is in favor of Woelfler's procedure, which he invariably employs.

Ricard mentioned a most interesting case of continuous vomiting after gastro-enterostomy for pyloric carcinoma. Ten days after the operation, as the incessant vomiting threatened the life of the patient, he reopened the abdomen, found the upper part of the duodenum greatly distended and the lower part collapsed. He performed entero-anastomosis. The vomiting ceased in a few hours and the patient recovered, to die eighteen months later from an extension of the disease.

Tuffier referred to the *difficulty in making a differential diagnosis in tumors of the liver.* If the question lies between a cystic and a malignant neoplasm, recourse is usually had to puncture. In many cases, however, if a careful examination be made of the hilum of the liver the presence of enlarged glands will determine with certainty the diagnosis of cancer. He also spoke of the ease with which hemostasis may be accomplished by pressure of the pedicle of the organ.

Gerard-Marchant presented specimens taken from a patient who died from peritonitis following rupture of an abscess of the liver. The abdomen was freely opened and an unsuccessful search was made for the site of perforation. Death followed in twelve hours.

At the Medical Society of the Hospitals January 22d, Bourneville showed two children of three and four years of age affected with *myxedematous idiocy* who had been *treated with sheep's thyroid.* Each child took daily for 166 days one-half a thyroid gland, that is, about half a gram. The treatment was then suspended for two months and then resumed for ninety days.

Under this treatment a great change was produced in the nutrition, and the fatty infiltration of the integument markedly decreased. During this period one child increased in length 11 cm., and the other 10 cm., that is, almost twice the natural growth. The mental development was also most marked.

FERRAND reported the case of a young man aged twenty, who became infected from a prick in the left index finger and developed axillary adenitis and septicemia with typhoidal symptoms. Death occurred twenty-six days after the infection. Inoculation of broth with splenic pulp furnished a pure culture of streptococcus, while the lesions detected at autopsy confirmed the diagnosis of grave septicemia. The interesting point in connection with this case is the fact that on the fifth day on account of the typhoidal symptoms the serum test was made, but without agglomeration either immediately or after preservation in the incubator. Two days later the axilla was incised but only bloody serum was obtained. As the typhoidal symptoms persisted, the serum test was repeated a few days later with a positive result. A second test was made two days after the first, likewise with a positive result. The case was, therefore, one in which the agglomerating reaction existed without the typhoid bacillus.

In discussing this case WIDAL thought that the investigations of Ferrand were not conducted with sufficient regard to scientific accuracy to be conclusive. Up to the present time, although the test had been applied in all countries, he had yet to learn of a case in which it was present in the absence of typhoid fever.[1]

FRANÇOIS-FRANCK at the session of the Biological Society held January 19, described the results of experiments which he had made on both dead and living animals with the thorax opened and closed, and both with and without curare to determine the *cause of death following the effusion of a liquid into the pericardium.* He found that the presence of a liquid in the pericardium by compressing the auricles keeps the venous blood from entering the heart. In order to overcome the intravenous pressure in a living non-curarised subject, the presence of the liquid in the pericardial cavity must be at least twice as great as the pressure in the veins.

CLAISSE and JOSUÉ experimented on seventy-two animals in order to study *pulmonary anthracosis.* In subjects with simple anthracosis, histologic examination showed absolutely no inflammatory reaction due to the charcoal dust, even when the animal had inhaled it in 260 sittings. A number of anthracotic animals were exposed to a number of unfavorable influences, but in the majority of cases the differences between the test and control animals was slight. An exception was seen in tuberculous animals and those in which the pneumogastric nerves had been divided. The conclusion was reached that the presence of coal dust in the lungs of a human subject is incapable of developing such ill-effects as have been attributed to it, namely, bronchitis, bronchiectasis, chronic pneumonia, phthisis, and anthracotic cavities. The coal dust in a measure may prepare the soil for these various affections and give them a somewhat peculiar anatomical and clinical character.

HARTMANN and DAQUEZ reported Jannary 30, *modifications of the blood which they ascertained to be present after splenectomy.* They also examined the blood of other patients on whom laparotomies had been performed. From comparisons of the results obtained they conclude that certain results are commonly found after various operations, while others are characteristic of splenectomy. Among the former are (1) a slight and transitory decrease in the number of red blood globules and the quantity of hemoglobin; (2) an increased leucocytosis, also transitory. Results which are characteristic of splenectomy are (1) a marked decrease in hemoglobin that lasts a long time; (2) a leucocytosis occurring slowly (one to three months) especially of mononucleated globules; (3) sometimes an eosinophil leucocytosis occurring still later (after three months).

SOCIETY PROCEEDINGS.

NEW YORK CLINICAL SOCIETY.

Meeting held November 27, 1896.

DR. ANDREW J. MCCOSH, president, in the chair.

DR. L. EMMETT HOLT presented a child aged fourteen months who was suffering from a tuberculous conjunctivitis. The patient had had a chronic purulent discharge from both eyes and the nose for some time. Her general appearance was that which formerly would have been regarded as typical of strumous ophthalmia. As the father was suffering from tuberculosis, it occurred to Dr. Holt to examine the discharge from the eyes of the child microscopically, and this being done it was found to contain a considerable number of tubercle bacilli.

DR. HERTER presented two patients for inspection, the first of whom gave the following history: He was forty-one years of age, and had had scarlet fever and syphilis, the latter complaint having existed during a period of ten years. Two months previously a hard, immovable and somewhat tender mass had made its appearance in the right umbilical region. His urine had increased somewhat in amount since that time, but its composition was normal; appetite good and bowels rather constipated. Upon examination with and without the aid of an anesthetic, the growth was found to be as described, extending from the region of the umbilicus to the anterior superior spine of the ilium, being round in shape and having smooth edges. It was rigidly fixed.

The second case was apparently one of cerebellar tumor, occurring in a laboring man thirty-two years of age. He had always been well until six years previously, when he had contracted syphilis. He used alcohol very moderately. Four years ago he began to complain of loss of memory, and his sight began to fail him, especially that of the left eye. Then a staggering gait developed, which soon became so pronounced that he was unable to walk, and a weakness of the muscles of the left side of the body and the right arm supervened. Under the administration of salicylate of mercury he gradually improved, so that power in the upper and lower extremities is now almost normal. Sensibility has been good at all times. The gait is markedly ataxic, and the speech slow and rather halting. Memory is poor. Plantar and epigastric reflexes are not obtainable. Vision fairly good, though the ophthalmoscope shows both optic nerves to be affected wtth atrophy.

---

[1] In the *Wien. Wochensch.*, January 16th, Jez reports a case of tuberculous meningitis in which the agglomerating reaction was present.—ED.

Dr. Herter considered the case to be of especial interest for the reason that, unlike most cases of brain tumor, headache or vertigo had never been present, there had been no vomiting at any time, and control over the sphincters had always been perfect. He had very little doubt as to the correctness of the diagnosis of cerebellar tumor, and thought it to be located near the median line. The patient had shown remarkable improvemont under systematic treatment.

In the discussion following the presentation of these cases, Dr. Abbe, who examined the first patient, said that the tumor appeared to be too large to be a misplaced kidney. It somewhat resembled a carcinoma, but was apparently not as tender to pressure as these growths usually are. He was inclined to think it an omental growth, and that an exploratory incision was indicated.

DR. KATZENBACH, in connection with the second case, agreed fully with the diagnosis that had been made, and related an instance of a somewhat similar case in which the patient complained of intense headache, and afterward became completely blind from atrophy of the optic nerves.

DR. L. EMMETT HOLT read a paper on

SOME PHASES OF TUBERCULOSIS IN EARLY LIFE,

(published in part in the MEDICAL NEWS of December 12th, 1896).

The discussion of this paper follows:

DR. W. P. NORTHRUP exhibited some drawings of lungs containing tubercular lymph nodes, in some of which there was no evidence of disease except in these structures. His belief was that in the great majority of cases in young children the lymph nodes were first involved, the extension to the lung being secondary. In one of these drawings there was a large cavity surrounded by a dense fibrous membrane two or three millimeters thick.

Dr. Northrup fully agreed with the statement made by Dr. Holt with regard to the importance of disease of the lymph nodes in the tuberculosis of very early life. In a series of 125 cases of tuberculosis he had found 13 in which the disease was limited to the lungs, and in 9 of these the process was practically confined to the lymph nodes. Regarding the intestinal tract, he had seen just one case in which there was obviously no primary lesion of the lymph nodes.

The temperature in cases of metastasis is always high, but its occurrence is not of especial diagnostic importance. The disease may be present in the person of a plump, well-appearing child, on the one hand, or in one who is poorly nourished and weak. With regard to inherited tuberculosis, the speaker related the history of a child of a tuberculous mother that at one time had been under his charge. The child died fifty-four days after birth, and upon autopsy the lungs were found riddled with cavities. During its short life there were no indications of infection. He was under the impression that but three or four well-authenticated cases of tubercular involvement of the placenta had been reported up to the present time. A child born of a tuberculous mother undoubtedly inherited a strong tendency to the disease, but there as yet has been no proof evolved that the affection itself is transmissible.

DR. DELAVAN said the question of the infectiousness of milk is an exceedingly important one, in connection with the study of tuberculosis. He had been called recently to a neighboring state to operate on a child for adenoids. He found her to be in the last stages of pulmonary tuberculosis. Upon inquiring it was discovered that she, as well as two other children in the same family, had been fed largely on the milk from a single cow, which, on examination, was found to be in a very poor and sickly condition. The other children showed no evidence whatever of disease. He referred to the danger of infection through the medium of the tonsils, and of various adenoid growths of the pharyngeal vault, and suggested the advisability of further study of the question.

DR. MENDELSON claimed that the statements made by Dr. Holt were founded largely upon hospital experience, as, for his own part, he met with but few cases in private practice of tuberculosis in children. He could recollect but two instances, and these were in exceptionally poorly nourished subjects.

DR. JACKSON was inclined to agree with the last speaker, and asserted that many cases of marasmus are mistaken for pulmonary tuberculosis. Clinical signs in children under two years of age are seldom of much value, except, possibly, when those of consolidation are well marked. The temperature is sometimes a guide to correct diagnosis if the patient is older than two years, but in the majority of instances it is valueless as indicating either the seat or extent of the trouble. He instanced the case of a child whom he was called to see who had had a severe attack of croup, and whose temperature ranged from 99° to 101° F. for several weeks subsequent to recovery. The parents were both tuberculous, and it was thought that the child had also become infected. A change of climate for a few weeks restored the patient to perfect health.

DR. SWIFT related a personal experience with two cases in which tuberculous infection had apparently occurred through the agency of the tonsils, one case being secondary to whooping-cough. He thought that the occurrence of dyspnea was a valuable diagnostic sign.

Dr. Brown said that he would like to ask three questions of Dr. Holt in connection with the statements contained in his paper, and these were, (1) if he considered that metastasis in tuberculous disease took place through the lymph or blood channels; (2) if the presence of tuberculous meningitis was necessarily secondary to traumatism, and (3) if in his experience with tuberculosis he had found in cases where the lungs were not the primary seat of the disease, if the liver was most frequently involved, the spleen next, and the kidneys last?

Dr. Holt, in reply, said that in 211 cases he had found the spleen involved in 88, the liver in 77, and the kidneys in 46. Regarding metastasis, he thought it most frequently occurred through the lymph channels. Tuberculous involvement of the meninges, in his opinion, was sometimes secondary to injury, but by no means necessarily so.

Referring to the frequency with which pulmonary tuberculosis in children is met with in private practice, he said that he had frequently been called in to see a child in which this diagnosis had been made, only to find it suffering from broncho-pneumonia. A naturally healthy child with good surroundings rarely develops phthisis. He thought in the instance cited by Dr. Jackson that the child might have really become infected, but that the tubercular area might have become encapsulated.

REVIEWS.

The Practice of Medicine. A text-book for Practitioners and Students, with special reference to diagnosis and treatment. By James Tyson, M.D., Professor of Clinical Medicine in the University of Pennsylvania; Physician to the Hospital of the University; Physician to the Philadelphia Hospital, etc. Illustrated. Philadelphia: P. Blakiston, Son & Co., 1896.

It is always a pleasure to read a new text-book on the practice of medicine, and particularly so when the author is a physician of wide reputation. In the field of general medicine, however, there is very little room for originality in ideas and theories, and the ground has often been covered during the past few years. Dr. Tyson states that his book has been written with special reference to diagnosis and treatment, and after a careful examination it can be said that this object has been thoroughly and completely attained. The ripe experience of years has been united to the full appreciation of modern methods, and the result is highly satisfactory.

The first section, of two hundred pages, is devoted to infectious diseases, with the exception of croupous pneumonia and acute articular rheumatism, which are classified under diseases of the respiratory system and constitutional diseases, respectively. This section is one of the best in the book, and a full historical account of each disease gives it special interest and value. Rules for prophylaxis and nursing are explicitly stated in every instance. The chapter on typhoid fever is one of the most comprehensive, but there are too many repetitions, and in the management of hemorrhage the author says that a hypodermic injection of ⅛ to ¼ of a grain shall be given, the student being left to suppose that morphin is meant. Hydrotherapy is fully described, and none of the complications, excepting hemorrhage, is allowed by the author to interfere with the baths. With the Burr portable bath-tub, however, even this complication does not interrupt the treatment. No stimulation is given during the bath excepting for special reasons or to entertain or comfort the patient. In the treatment of the malarial fevers no mention is made of the use of methylene blue. The recent acquisitions to our knowledge of the plasmodium are described in a remarkably clever style.

In the chapter on cholera, an attempt is made to give in full the bacteriologic methods of examination for the bacilli; but we cannot endorse them as being sufficiently complete for a positive diagnosis. The treatment by hypodermoclysis and by enteroclysis is admirably and fully stated. In inflammation of the middle ear, occurring in scarlet fever, the author recommends paracentesis when the tension is extreme! We would not advise waiting for extreme tension, but would prefer to perforate early. This measure cannot be productive of harm if carried out with the usual antiseptic precautions, and much anxiety and danger may thus be averted. In the discussion of the treatment of pertussis, it would seem that bromoform is worthy at least of mention. In the treatment of pyemia, surgical procedures as mentioned by the author stand preëminent, and we feel that his recommendation of atropin, oil of erigeron, ergot and agaricin is almost useless.

In the light of our present knowledge, it seems quite incomprehensible that the so-called idiopathic tetanus still receives recognition in modern text-books of medicine. True tetanus can only be caused by the specific bacillus, and it is only in cases where no external lesion is *apparent*, that the old term "idiopathic" still seems to be used. We are fully aware that some cases of tetanus run a milder course than others, and that the mortality varies greatly, but if a diagnosis of tetanus be made, we must be prepared to accept the presence of the bacillus, whether or not it can be demonstrated. In the future we sincerely hope that this classification will be changed.

Section II deals with diseases of the digestive system, and the facts and methods of diagnostic technic and chemical examination are clearly and exhaustively given. Fifteen pages are devoted to appendicitis, and the history of that disease receives the attention due to so important a topic. In discussing the morbid anatomy of croupous pneumonia, the author says: "A stage beyond gray hepatization is sometimes spoken of as a stage of yellow hepatization. In this stage the lung has assumed a more yellow appearance, it is much softer, almost liquid in consistence, and more like pus. . . . . The stage of gray hepatization is the stage of beginning resolution, while that of yellow hepatization is probably one whence recovery is impossible, as it is only seen *post-mortem*." In the first place, how any stage of hepatization can be *seen* except *post-mortem* is a mystery. It has been conceded, in autopsies made at this stage in cases dying from other causes, that yellow hepatization is present in *all* cases going on to recovery, and that it is simply due to a great increase in the number of leucocytes undergoing the process of fatty degeneration. The author evidently had in mind the condition known as purulent infiltration, caused by a mixed infection, occurring either primarily or secondarily. In the treatment of pneumonia, the use of ice-cold applications to the chest is favored. Venesection early, rather than the use of veratrum viride, is properly recommended.

The section on diseases of the nervous system covers three hundred pages, and the general symptomatology is superbly written, in fact we do not know of any text-book of general medicine which deals with this subject in so complete and instructive a manner. Space does not admit of a more detailed review of the subjects dealt with in this work. At the end of the book a summary of symptoms following over-doses of poisons is given, to which is added a table of minimum doses which have caused death, and maximum doses followed by recovery; also, an appendix with tables for converting the English into the metric system, and the reverse. The index of ten pages is by far inadequate for so voluminous a volume. The illustrations are mostly good, but we think those of nasal specula and an ordinary spray apparatus out of place in a work on medicine. The type, paper and binding are good, but many typographical errors are noticed. The book as a whole is a good one, embodying as it does much personal observation and reading, and is deserving of high commendation.

APPLIED BACTERIOLOGY. An Introductory Handbook for the Use of Students, Medical Officers of Health, Analysts, and others. By T. H. PEARMAIN and C. G. MOOR, M. A. Cantab, members of the Society of Public Analysts, Associates British Institute of Public Health, etc. University Series. Pp. xiii, 360. London: Baillière, Tindall & Cox, 1897.

THE contents of this book are properly suggested by the title. The authors have handled the subject in an easy, familiar style, which renders it attractive to the reader. The classification and methods of reproduction of microorganisms might have been more clearly defined for the needs of those beginning the study of bacteriology. The description of apparatuses and the preparation of the nutrient media are satisfactorily given; but more than six pages are devoted to the description and management of a certain gas-regulator. The various methods of staining and mounting bacteria on covers and in sections follow.

"Immunity and Susceptibility" are admirably discussed, but under the heading of "Practical Disinfection" no mention is made of the uses of formalin vapor.

Six excellent chapters are devoted to the many infectious diseases, and in each instance a history and description of the organism, if known, is given, as well as the growth on the culture media, the methods of examination, occurrence and distribution, pathogenesis, and preventive measures; but not a single reference is made to bubonic plague. The serum treatment of typhoid fever, cholera, and diphtheria is clearly handled, and the technic of making injections is given in detail.

We do not agree with the statement that "the Finkler-Prior spirillum is the only one which is at all likely to be confounded with Koch's 'comma.'" The authors say that Lustgarten's bacillus is probably the specific organism of syphilis; and that the streptococcus described by Klein in 1882 is probably the specific cause of scarlet fever. These views should not have been so dogmatically expressed.

In the references to recent literature on malaria, no mention is made of the superb monograph of Thayer and Hewetson. The succeeding chapters describe the yeasts, molds, and protozoa at length. The section on the examination of water, milk, air, soil, and filters is exceedingly well written. A short description of the construction of steam-disinfectors closes the text. The book is well printed on good paper, and the wood-cuts are satisfactory. At the end of the book are a number of colored plates taken from the recent admirable work of Lehmann and Neumann, yet without giving due credit.

QUAIN'S ELEMENTS OF ANATOMY. Appendix. Superficial and Surgical Anatomy. By PROFESSOR G. D. THANE and PROFESSOR R. J. GODLEE, M.S. Illustrated by twenty-nine engravings. Tenth edition, Pp. 76. Longmans, Green & Co., London, New York, and Bombay, 1896.

BY the publication of this brief appendix on superficial and surgical anatomy, the tenth edition of Quain's "Anatomy" is finished. The work is now complete in nine parts, which are conveniently bound and sold separately. The appendix to the work contains much that is old and little that is new, as might be expected; but the matter is put into accessible form and is illustrated by several excellent new plates. The pages devoted to endocranial blood-vessels and cranio-cerebral topography are particularly valuable, and the exact location of the mastoid antrum, the lateral sinus, the middle meningeal artery, and the cerebral lobes are so clearly indicated in the colored plates which accompany the text that this section of the book will be often referred to in connection with brain surgery.

In the sections on inguinal and femoral hernia, the fascial planes, and their relations to the bones and soft parts are clearly described and are still more clearly drawn. It is difficult to suggest any addition by which the anatomical basis of the usual forms of hernia could better be brought before the mind.

The section on the abdomen is, unfortunately, meager, and some of the space which has been given all through the work to details which belong to descriptive rather than regional anatomy might well have been devoted to a more thorough description of the position of the abdominal organs.

THE MEDICAL RECORD VISITING LIST FOR 1897. New York: Wm. Wood & Co.

THIS handsome visiting list will maintain its reputation for beauty and usefulness in the edition for the new year. It contains many lists and tables for emergencies and for rapid consultation, and is in every way commendable.

New York County Medical Society.— Professor Osler of Johns Hopkins University, read a paper before this society on Monday evening, February 22d, on the "Diagnosis of Malarial Fever." During his remarks in the discussion that followed, he made the somewhat startling assertion that death from malaria in the region north of Mason and Dixon's line is almost unknown.

THE MEDICAL NEWS.
A WEEKLY JOURNAL OF MEDICAL SCIENCE.

VOL. LXX. NEW YORK, SATURDAY, MARCH 6, 1897. NO. 10.

ORIGINAL ARTICLES.

THE DIAGNOSIS OF MALARIAL FEVER.[1]

BY WILLIAM OSLER, M.D.,
OF BALTIMORE;
PROFESSOR OF MEDICINE IN THE JOHNS HOPKINS UNIVERSITY.

AMONG a multitude of points of great interest in malarial fever the following may be emphasized:

1. It was the disease best known to the old Greek and Roman physicians, some of whom gave very clear clinical pictures of the chief varieties.

2. It remains, after two hundred years, the only acute infectious disease for which we have a positive specific.

3. It is the most important known disease due to protozoon parasites.

4. North of Mason and Dixon's line physicians are prone to diagnose malaria for other diseases; south of the line they are more prone to diagnose other diseases for malaria; in both regions it is a source of greater errors in vital statistics than any other affection.

It is not my intention to bore you with any detailed account of the hematozoon malariæ, but I would remind you that there are three well recognized varieties. (1) The tertian organism, which matures in forty-eight hours and produces quotidian paroxysms if two groups are present, tertian if there be only one. This is the common parasite of the simple intermittents of the spring and early autumn. (2) The quartan parasite, which has a cycle of development of seventy-two hours, and, if only one group of organisms is present, causes the regular quartan intermittent; if two or more groups are present, the paroxysms may be daily or every other day. The quartan parasite is a rare form. There have been only about fifteen cases among 1000 examined at my clinic. (3) The parasite of the irregular malarial fevers (estivo-autumnal form)—the remittent, continued, and pernicious types. This variety is smaller, less easily recognized, is not so abundant in the peripheral circulation, and, in the pernicious forms, may have curious seats of election, as in the brain or intestines. It is further characterized by the development of the crescents, a distinctive and characteristic form of great moment in diagnosis.

The recognition of the invariable association of these parasites with all forms of malarial fevers, of their etiological relation to the disease, and of their importance in diagnosis, has resulted from the labors of Laveran, and of his followers in Italy, and in this country. I cannot forbear a word of warm commendation of the way in which our Italian colleagues have persistently followed, and with such success, the many problems connected with the life history of the parasite. Anyone who wishes to keep abreast of the world's work on malaria must know the Italian literature. Much remains to be worked out—the relations of these varieties to each other, the significance of the crescents and of the flagellate form, the life history outside the body, and the mode of infection. Is it a facultative parasite? Is it possible that in infected districts persons may harbor it and show no symptoms, as is the case with the filaria and the anchylostoma? How long may it lie *perdu*, so to speak, in the body?—surely questions enough to satisfy the cravings of the younger generation of workers.

A word before I pass on to the subject in hand. To obtain a correct knowledge of the forms of the malarial parasite requires months of careful study, with plenty of material. There have been papers published in this country and in India which bear ample evidence that the authors have approached the problem without due technical preparation. Two educational points are particularly to be noted: the changes which the red corpuscles undergo on a slide after twenty-four hours on the warm stage, and the irregular forms of vacuoles which are not infrequent in the red corpuscles in some fevers, particularly scarlet fever and measles. I would urge particularly as a *sine qua non* in all doubtful cases, and especially in supposed mixed infections, as with malaria and typhoid fever, that cover slip specimens of the blood be preserved, which, if necessary, could be submitted to the judgment of an acknowledged expert.

The recognition of malaria is fortunately in a large majority of all cases a very easy matter. The subject for discussion may be indicated under three headings: 1. The diagnosis of the regular malarial intermittent fevers. 2. The diagnosis of the irregular remittent and pernicious forms. 3. The spurious malaria of the Health Boards.

1. THE SIMPLE INTERMITTENTS.

The tertian infection, the only common one in this country, is characterized by a paroxysm developing at the end of forty-eight hours, if a single group of parasites is present; at the end of twenty-four hours, if two groups exist, one of which maturates every day. There are three features by which an ague can be recognized:

---

[1] Read before the Medical Society of the County of New York, February 22, 1897.

(*a*) The character of the febrile paroxysms. Take any large series of carefully recorded temperature charts, such as have been made in my wards during the past seven years,[1] and it is found that the duration of the pyrexia from the rise above 99° F. to the fall to normal is from eleven to twelve hours, rarely shorter, still more rarely longer.

(*b*) The blood shows the hematozoa in all stages of development. Practically they are never absent in uncinchonized individuals. There is no leucocytosis.

(*c*) The administration of quinin checks the further development of paroxysms and causes a rapid disappearance of the parasites.

During last year I saw in private, or there were brought to my wards, cases with intermittent paroxysms of fever believed to be due to malaria, but which subsequently proved to be the following conditions: abscess of the liver, tuberculosis, influenza, gonorrhea, endocarditis, otitis media, gall-stone fever, post-partum anemia, typhoid fever, and septicemia. There are other affections, such as syphilis and many obscure septic infections, with which recurring chills may be associated. There are also remarkable cases of cryptogenetic septicemia with daily chills—cases in which tuberculosis and malaria can be almost positively excluded. Dreschfeld of Manchester has described a form of this as idiopathic intermittent fever of pyemic character. It must be confessed that the regularity of the chills, often of a quotidian or tertain type, and the obscurity of the cause, make the disguise very complete. The three points just referred to suffice, as a rule, to clear up the diagnosis. The length of the paroxysm in septic cases is rarely so long and not so fixed in recurring attacks. Shorter periods of pyrexia, six to eight hours, are the rule; occasionally they are longer, eighteen to twenty-four hours. This point, together with the presence of a leucocytosis, the great increase in the blood plates, the absence of the hematozoa, and the resistance to quinin, serve to exclude malarial infection. To one or two of these conditions I may refer briefly.

It is not sufficiently recognized in the profession, particularly in malarious regions, that pulmonary tuberculosis very frequently sets in with chills and fever. In Baltimore I not infrequently see cases in which the patient has been treated persistently with quinin, until the aggravation of the cough, or the occurrence of hemoptysis has aroused the suspicion that the lungs were affected.

Abscess of the liver is almost always at first treated for malaria. The recurring chills and fever, and the sallow tint, lead, not unnaturally, to this mistake, which is made even in regions in the North which are quite free from paludism.

Another condition of the liver is a common source of error, namely, gall-stone fever. I do not refer to the chill during the passage of the gall stone, nor to the recurring chills in the pyemia of suppurative cholangitis, but to the recurring paroxysms of intermittent fever for months or even for years in connection with the lodgment of a stone in the common duct.

II. THE IRREGULAR MALARIAL FEVERS.

In reality the chief difficulty in the diagnosis of malaria is in the recognition of the remittent fevers which simulate typhoid, of certain pernicious types with special localization, and of certain chronic infections. Every year we have a few cases of malarial remittents which are at first mistaken for typhoid fever and tubbed. I show you here a chart of the last case of this kind.

The patient, Edward Reip, aged twenty-one, was admitted October 2d, complaining of headache and pains through the body. He had had malaria five years ago; otherwise there was nothing of special moment in his history. On the 29th of September, three days before his admission, he had a wetting, and on the following morning awoke with a violent headache, and felt so badly that he worked with difficulty. He stopped work the day before admission. He felt cold, but had no chill. He had lost his appetite. There was no nausea and no vomiting.

When admitted his temperature was 105° F., face was slightly flushed, the tongue furred and white. The examination was negative with the exception of the spleen, which was enlarged and slightly tender. The patient looked very ill, and his temperature on the evening of admission rose to 106° F., and he was given a tub bath. For seven days this patient was treated for typhoid fever, and during this time he had thirty-two tubs. He had no chills, no sweats; the tongue was furred, the cheeks flushed, lips red; the spleen was readily palpable. The blood was examined by the house physician each day, sometimes twice a day, with negative results. On October 9th Dr. Thayer found in the peripheral blood a number of actively moving ameboid bodies. On the evening of the 9th he was given ten grains of quinin hypodermically, and then five grains every four hours. His temperature fell gradually and reached normal three days after beginning the administration of quinin. In this patient the anemia did not develop until after the end of the first week of the disease.

---

[1] See the Monograph by Thayer and Hewetson, "Johns Hopkins Hospital Reports," vol. v., and Dr. Thayer's article in vol. i. of the recently issued "American System of Medicine," by Loomis and Thompson.

I mention this case in detail because it illustrates a very important point in the clinical history of these cases, namely, that in certain forms of infection with the organism of the irregular malarial fever the parasites are at first very scanty in the peripheral blood, and may be, in fact, overlooked for some days.

With us it has been very much more common to mistake malaria for typhoid fever than typhoid fever for malaria. The following are the important points of differentiation:

First. The mode of onset.—In malarial remittent fever there is not the initial period of malaise and ill-health; the onset is more sudden; chills are much more frequent. They are not, however, always present, as in the case of which I have just spoken. On the other hand, chills at the onset of typhoid fever are not very uncommon. Of 79 cases treated during the sixth year of hospital work, in which this point was inquired about particularly, there were 13 in which the disease began with shaking chills. Epistaxis is rare in malaria.

Second. The fever, which presents three points of great importance in the differentiation.

(*a*) The slow, step-like ascent to the fastigium is not met with in malaria. The rise is abrupt, and on the first or second day the temperature may reach 104° or 105° F. You will see in the chart passing around that the temperature on the third day in that patient reached nearly 106° F. in itself almost enough to exclude typhoid fever.

(*b*) The malarial remittents never have the remarkable continuous type of fever which we see in typhoid after the fastigium is reached. No other disease, except pneumonia, presents the same persistent pyrexia, with perhaps not more than a degree or a degree and a half of diurnal variation. This is characteristic particularly of the second week of the disease, or from the fifth to the twelfth day. In the estivo-autumnal infections the remissions are, as a rule, marked—two, three, and even four degrees.

(*c*) In the later stages, say in the third week, when in typhoid fever there are wider excursions and marked remissions, the pyrexia in the remittent fever becomes much more broken, is apt to be more intermittent in character, and the temperature may even be subnormal for several hours of each day.

Third. The general appearance of the patient.—Walking through a ward containing malarial intermittent cases and typhoid fever patients one can usually pick out readily those with the former disease. The early anemia and sallowness are very characteristic. This is not the case with malarial remittent fever. During the first week the aspect may be typically typhoidal, the expression dull and heavy, and the cheeks flushed. Marked anemia and the sallow tint may not develop until the patient has been under observation for a week or more.

Fourth. —The gastro-intestinal, bronchitic, and nervous features offer less valuable criteria of differentiation. Herpes on the lips, when present, is important because of the great rarity in typhoid fever and the great frequency in malaria. The tongue in remittent fever is usually more coated, pasty, and white early in the disease. Bronchitis is common in both. Mental hebitude and delirium, while more common in typhoid fever, are not at all infrequent in the severer types of the estivo-autumnal fever.

Fifth. The examination of the blood.—The very first slide looked at may give the diagnosis. In other instances repeated examinations may be necessary, and the case to which I have referred is not at all unique in our experience. The paucity of the organisms in the peripheral circulation is very unfortunate just in these cases, as it may leave the diagnosis in doubt for several days. A systematic examination of the blood in any estivo-autumnal form is sure to be rewarded by the detection of perfectly distinctive forms, if not of the intracellular, of the characteristic crescents. Widal's test, too, will prove of great use. You will notice in the chart passing around that it was not present on October 8th, the eighth day of the patient's illness, and the day before the organisms were found in the blood, and this, with the irregular temperature, made us renew our efforts to discover the parasite.

Sixth.—Quinin has no influence on typhoid fever. Properly administered, it checks the malarial remittent fever in from two to four days.

There are other points of differentiation, but these are the most important.

In connection with this question there arise two important points for discussion: How far, in paludal regions, does typhoid fever present malarial aspects? It is the rooted and grounded belief of a very large section of the physicians of this country that typhoid fever very often presents "malarial features." The phrase is on their lips constantly. Failure to recognize the extraordinarily protean character of the disease is in the main responsible for this delusion, behind which lies a sort of feeling that a fever with malarial aspects is less apt to be serious. So far as my personal experience is concerned, typhoid fever is a singularly fixed disease in its composite picture, as taken, say, in centuries of cases. I saw the disease for ten years in Montreal, the General Hospital of which offered a very rich field for its study. The cases which came under my care during five years at the University and Blockley Hospitals in Philadelphia presented no essential changes. Many of the cases came from regions infected with malaria. During the seven years and nine months in which the Johns Hopkins Hospital has been opened, there have been in my wards more than five hundred cases of typhoid fever. A considerable number of these came from the outlying districts of the city, in which malaria is very prevalent, and from which our cases of that disease come. Any one may judge from the studies on typhoid fever, issued in Reports of the Johns Hopkins Hospital, Vols. IV. and V., that the disease presents no variations from the universally recognized picture of the disease. We know nothing of typhoid fever with malarial features; on the other hand, we know a good deal, as you may judge from the chart, of malaria with typhoid features.

How often do combined infections occur with the hematozoa and Eberth's bacillus? Very seldom; much less frequently than with the pneumococcus and with the ameba coli. Among the 1000 cases of malaria and the 500 cases of typhoid fever which have been at my clinic, almost every one of which has had a blood examination, there has been but one doubtful case of double infection. So far as I know, Dr. Gilman Thompson's cases are the only satisfactory ones observed in this country. The subject is one deserving of careful study. We have been in the habit of making blood examinations in all of our typhoid cases, and as the double infection is usually with the tertian organism, I can speak with some measure of positiveness as to the accuracy of our results. I would ask particularly that in doubtful cases cover-slips be kept for expert examination. This is not a matter to be left in the hands of the inexperienced house physician. In other double infections quinin causes the hematozoa to disappear within a few days, and the case proceeds without showing signs of special influence, and this was the case, I believe, with Dr. Thompson's patients.

Certain symptoms, particularly chills and sweats, are prone to deceive the physician who has not learned to recognize them as not infrequent events in typhoid fever, associated with complications or with septic infection.[1]

I need scarcely here refer to other forms of irregular malarial fever—the more pernicious types. They are not very common with us, though in the autumn we have to be on guard constantly to avoid mistakes, and we have, as a rule, one or two fatal cases a year.

III. SPURIOUS MALARIA.

What is spurious malaria? I do not know. One form of it is a serious and very fatal disease, killing, according to the last United States Census Report, in New York as many persons as does typhoid fever, in Brooklyn about one-third as many more. I suspect the Eberth bacillus, not the plasmodium malaria, is responsible for the major part of these cases. Other maladies, a motley host, from headache to biliousness, from keratitis to chilblains, are attributed to "a touch of malaria." Any slight ailment with a periodic tendency, any dubious trouble for which a diagnosis is not forthcoming, is put in the same category. While I do not deny that in regions where malaria is endemic, and everybody comes under its influence, many obscure troubles follow in its train, I claim that the disease in the temperate regions of this country is well defined and easily recognizable, that north of the Chesapeake the fatal forms have become so rare that no health board should take a death certificate signed "malaria" without investigation, and, lastly, that the widespread belief in an occult influence of the disease, in masked forms, and in the modification by it of other affections, has no rational basis of support.

It is just eleven years since I began the study of malarial fever in the Blockley Hospital, Philadelphia—a skeptic as to the value of Laveran's work, to which attention was called in this country by Surgeon-General Sternberg and Dr. Councilman. I soon became convinced of its truth, and the results of my study of seventy cases was published in 1887. Since that time, at certain seasons, I have had almost daily opportunity to see malarial fever, and I have of late years been fortunate in having as my associate Dr. Thayer, who has made a special study of the disease, and in Baltimore has kept us in touch with the progress of knowledge in this department. A widened experience has only served to strengthen the conviction that in the practical diagnosis of the infectious diseases, the discovery of the hematozoa of malaria by Laveran takes rank with the finding of the tuberculosis bacillus by Koch.

BLOODLETTING IN PNEUMONIA.

By ROYAL W. AMIDON, M.D.,
OF NEW YORK;
PROFESSOR OF THERAPEUTICS IN THE WOMAN'S MEDICAL COLLEGE OF THE NEW YORK INFIRMARY.

MORE than 41,000 people died in New York City during 1896, and of these 5383, or nearly one-seventh, died of pneumonia. These figures do not include deaths where pneumonia was a complication. We have in pneumonia, therefore, a disease which contributes more to our death-rate than any other single disease. It is a lamentable fact that, in spite of our boasted advances in medicine, the mortality from pneumonia is greater to-day than it was fifty years ago. Townsend and Coolidge,[1] from a study of all the cases of this disease treated at the Massachusetts General Hospital from 1822 until 1889, one thousand in number, very ingeniously conclude that this increase in mortality is deceptive, and is entirely independent of treatment. The average mortality in the sixty-seven years reviewed by them was twenty-five per cent., ranging from ten per cent. in the first decade to twenty-eight per cent. in the last. They say, "This increase is deceptive, for the following reasons, all of which were shown to be a cause of a large mortality: (*a*) The average age of the patients has been increasing from the first to the last decade. (*b*) The relative number of complicated and delicate cases has increased. (*c*) The relative number of intemperate cases has increased. (*d*) The relative number of foreigners has increased. . . . These causes are sufficient to explain the entire rise in the mortality. Treatment which was heroic before 1850, transitional between 1850 and 1860, and expectant and sustaining since 1860, has not, therefore, influenced the mortality rate," nor has treatment, they add, "influenced the duration of the disease or of its convalescence."

---

[1] "Chills in Typhoid Fever," *University Medical Magazine*, November, 1895.

Statistics taken from the reports of the New York Hospital show a like increase in the mortality from pneumonia, and I think, are more valuable, as they are based on a much greater number of cases.

Years.	*Mortality per cent.*
1834–1843	25.4
1844–1853	25.7
1854–1863	23.8
1864–1870	27.7
1870–1877	Hospital closed.
1877	New hospital opened.
1877–1886	38.8
1887–1895	34.7

As far, therefore, as hospital statistics can be relied upon as a guide, the mortality from pneumonia has increased ten per cent. or more in fifty years. We have the explanation of this increased mortality, according to Townsend and Coolidge, and they state it as their positive opinion that change of treatment has not influenced the mortality rate. Such an explanation is soothing to pride and the conscience, but I, for one, am not satisfied with it, and am fully convinced that the increased mortality in pneumonia is partly due to a change of treatment, which necessarily has been a change for the worse. In the years from 1834 to 1853, at the New York Hospital, where the mortality was a little over twenty-five per cent., the main factors in treatment were, first, an initial smart purge; second, early, copious and often-repeated bloodletting; third, increasing doses of tartar emetic, and, fourth, blisters to the chest, generally after the fever had subsided. In the years from 1854 to 1863, when the lowest mortality, 23.8 per cent., was recorded, the treatment was on about the same lines, but much less heroic. The initial purge was given, the patient was generally bled, but not heroically, and seldom more than once, tartar emetic was given in sudorific doses only, and blisters were not much in vogue. In the years from 1864 to 1869, the treatment was, as Townsend and Coolidge call it, "expectant and sustaining," and the mortality was 27.7 per cent. In 1870 the old hospital was abandoned, and the first decade in the new hospital, aseptic throughout, from 1877 to 1886, showed a mortality of 38.8 per cent. The treatment at this period was largely stimulating (alcohol, digitalis, etc.), and antipyretic with drugs, mostly quinin, depletion and derivation being confined to dry-cupping and mild purgation. During the last nine years, 1887 to 1895, the mortality has apparently diminished somewhat, having been 34.7 per cent. During this period antipyretic drugs have been used, also vascular sedatives (other than bloodletting) and stimulants; but during this time some agents promoting oxidation and elimination, principally ice-bags and cold baths, have been sparingly employed, many think, with advantage.

It would seem that our modern notions as to the pathology of pneumonia have helped us very little in the treatment of the disease. In 1840, when pneumonia was looked upon as a simple inflammatory affection, Craigie laid down its treatment as follows: (1) An initial purge and free venesection, both sometimes, the latter generally, repeated; (2) tartar emetic in vascular sedative and diaphoretic doses; (3) diluent drinks and diuretics (chiefly nitre) to keep the kidneys active; (4) blisters to the chest, generally as the fever began to subside. The bowels were kept rather loose and the air of the room constantly cool. This treatment resulted in a hospital mortality of about twenty-five per cent., while, fifty years later, the disease being classed as infectious, the mortality is ten per cent. higher.

In our flight after microbes may we not overlook some very essential but homely details of treatment? Our knowledge does not enable us to kill the pathogenic germs, hence our treatment should be in the direction of oxidizing and eliminating the poison they generate, relieving the mechanical disturbance created by consolidation, and supporting the patient until the toxic storm has passed. The latter necessity has long been met by the administration of nutritious liquid food and alcohol The importance of intensifying oxidation by cold fresh air, by oxygen, and by local cold applications and cold bathing, is daily being more appreciated, while the re-establishment of secretion and elimination by skin, kidneys, and bowels, principally the two latter, is hardly less important and is brought about partly by the cold and partly by salin diuretics and cathartics.

---

[1] "The Mortality of Acute Lobar Pneumonia." Tr. Am. Climatological Assn., 1889.

The mechanical disturbance produced by intense pulmonary congestion and consolidation has been much neglected of late years. I advance the suggestion that obstruction of the pulmonary circulation and consequent embarrassment, weakening and dilatation of the right heart and backing up of venous blood is not caused by, nor commensurate with, pulmonary consolidation. Theoretically, we expect speedier cardiac embarrassment where large areas are hepatized; practically, it would seem as though the intense and general pulmonary congestion often present, and sometimes occurring with an insignificant amount of solidification, offered sufficient resistance to the pulmonary circulation to explain all symptoms dependent thereon. Explain its cause in any way we please, we know that, sooner or later, in all bad cases of pneumonia, the right heart never empties, venous distension occurs, the whole heart begins to fail from dilatation and want of oxygen, the pulmonary congestion is intensified and pulmonary edema ends the scene.

For averting or relieving this mechanical condition, depletion is the only rational procedure, and, when weighing the claims of depleting agents, there is found only one possessing the advantages of simplicity, safety, speed, and efficacy, and that is the sudden abstraction of a variable but considerable amount of venous blood. Diaphoresis is insufficient, diuresis too slow and uncertain, safe catharsis too slow, speedy, effective catharsis too dangerous. Judicious venesection has none of these drawbacks and is only kept from its deserved sphere of usefulness by a mouldy tradition of ancient immoderation.

The teachings of nature should never be ignored, and for that reason I append brief notes of two hitherto unpublished cases of pneumonia in which spontaneous hemorrhage, followed as it was by speedy improvement, seemed conservative if not curative.

The first case was observed in 1892 by Dr. Jennie M. Richardson of New York, who kindly allows me to report it.

The patient was a rachitic girl of five years. On January 18th she complained of headache and pain in the right side. She had anorexia, fever, and a severe cough. Two days later she coughed up considerable red, frothy blood, and experienced marked relief. Blood-stained sputum persisted for several days. When first seen on January 23d she had all the outward indications and physical signs of croupous pneumonia. Her temperature was 39.3° C. (102.8° F.), pulse 140, respiration 52. During the morning of January 24th she complained of a pain in her side, and at 1.30 P.M., after a fit of coughing, there was another hemoptysis of about 30 c.cm. (℥ i) of red, frothy blood. Relief from the pain followed the hemorrhage, but the child remained feverish, restless, and wakeful. January 25th there was improvement in all symptoms, the temperature being 38.3° C. (101° F.), pulse 132, and respiration 33. The next day convalescence was assured.

The second case was seen in 1894 by Dr. Miriam T. Runyon of New York, by whose permission it is here reported.

The patient was a previously healthy girl of seven years. At 10.30 A.M. on the fourth day of a typical pneumonia, the child had a temperature of 39.4° C. (103° F.), pulse of 128, and respiration of 48. At 12.30 P.M. she had a severe nose bleed lasting nearly two hours. The mother saved 270 c.cm. (℥ ix) of blood. Immediate improvement and relief from pain followed. At 4 P.M. the temperature was 36.7° C. (98.2° F.), pulse 100, and respiration 28. Uninterrupted and rapid recovery supervened.

It is unnecessary to say that both these cases were very intelligently treated, the latter by calomel, diuretics, and external cold, but neither showed marked improvement until local congestion was relieved by sudden depletion. In another case, reported by Dr. D. A. Staunton[1] of Lexington, N. C., a profuse hemorrhage from the bowels was followed by very striking but not so immediate improvement.

If we see spontaneous hemorrhage, provoked by irrepressible congestion, so beneficial, why should we hesitate to resort to a timely employment of so harmless and potent a remedy? Why, indeed, unless we are slaves to fashion, even in medicine and incapable of throwing off a blind, unjust prejudice!

DISEASES OF THE FRONTAL SINUSES AND THEIR TREATMENT.

BY FRANK WISTER THOMAS, M.D.,
OF PHILADELPHIA.

IN considering diseases of the frontal sinuses it is necessary to recall the anatomical relations of the parts in order to appreciate the symptoms presented. The sinuses may be described as two irregular triangular pyramids, each having an orbital plate of the frontal bone as a floor, two of the sides of each being formed by the inner and outer plates of the frontal bone, and the remaining side of each being formed by the septum, which is so frequently perforated as to render the sinuses pathologically one cavity. This region is lined by mucous membrane which is continuous on each side through small openings or infundibula with the mucous membrane of the nasal chamber. In some subjects foramina offer communication with the ethmoidal sinuses. Apart from those due strictly to traumatic causes, all diseases of this locality originate in the nasal membrane and present such modifications of the various catarrhal processes as are consistent with the nearly closed condition of the chambers. They may be classified as acute and chronic catarrhal inflammation, mucocele, and abscess or empyema, in addition to which we have such extraordinary conditions as are produced by foreign bodies, as the entrance of insects, or the lacerations and punctures due to wounds.

---

[1] *North Carolina Med. Jour.*, March, 1889.

Acute catarrh of the frontal sinuses is present in a minor degree in nearly all cases of acute coryza in the adult, but retention diseases, as mucocele and empyema, are exceedingly rare. Dr. B. Alexander Randall of Philadelphia reports that in a practice of over 1200 cases yearly, requiring nasal examinations, he has not met with one case of empyema that was strictly his own case; and of 2237 nose and throat cases reported last year from the Brooklyn Hospital only three cases of catarrh of the frontal sinuses are mentioned. As hospital statistics necessarily contain a larger proportion of exceptional cases than is to be found in private practice, I addressed communications to a number of gentlemen engaged in nasal practice, in this and other cities, and from all I have received assurances of the extreme rarity of the conditions under consideration.

The symptoms of catarrh of the frontal sinuses are those of ordinary acute coryza plus frontal and supra-orbital headache of a boring and persistent character, increased by movements or by mental effort or by the use of alcohol, and occasionally accompanied by nausea and vomiting. Pressure at the internal angle of the supra-orbital ridge usually occasions intense and severe pain. When the inflammation becomes chronic and the mucous is retained, the condition known as mucocele exists. It may be produced by any cause which obstructs the infundibulum, and while usually unilateral, may affect both sides. Sometimes the distension is so great that crepitation may be heard and felt upon pressure over the affected region. In rare instances, also, a soft fluctuating tumor forms at the inner angle of the orbit. One gentleman, with a large hospital and private practice, informs me that he has only seen one such case.

Abscess, or empyema of the frontal sinuses, is only to be differentiated from mucocele by the greater severity of the general symptoms, by the creepings or positive chill of the pyemic state, and by the purulent rather than the mucous discharge from the nostril. When the obstruction of the infundibulum is complete we may have either the internal subsuperciliary tumor, before mentioned, or, from backward pressure, brain symptoms, which may terminate in a purulent meningitis. There is one symptom which has been observed by Dr. James Darrach, as occurring in at least two cases, which came under his observation, the significance and constancy of which, are uncertain. This consists of an intermittent feeling of falling, hardly a vertigo, but rather a sensation of pitching forward, with loss of muscular coördination. In one of the cases reported, the condition was somewhat relieved by blowing the nostril, and completely disappeared after the discharge of a large quantity of pus through the nasal outlet. So marked was the symptom that the doctor was summoned by the patient, not to attend a nasal, but what was regarded as a brain, condition.

Answers to communications addressed to a number of specialists concerning this symptom elicited little that is satisfactory, only two of my correspondents having noticed the symptom in any degree. One speaks of having observed a slight dizziness, and another noticed vertigo in one case of specific origin. As to the reflex or anatomical cause of this condition, clinical observation will probably clear up the question if its frequency and constancy are ever studied. While at first inclined to look on the cause as due to a disturbance of the cerebral circulation, the answers from my correspondents lead rather to the view of a reflex origin, for the reason that cerebral circulatory disturbance must be present in all cases of mucocele or empyema; and yet from numbers of cases reported I can find only the four cases of vertigo mentioned, one physician reporting three cases of unassociated empyema, and two cases associated with disease of the ethmoidal cells, but even in the latter cases no symptoms of vertigo were observed. These facts, taken into consideration with the established observation that peripheral irritation of the trigeminus at times produces "nasal vertigo," would point to the reflex origin of the symptom in the disease under consideration.

As regards treatment little can be said except that the nasal chambers must be kept free and clear by means of various alkalin sprays and astringent applications to allay local irritation; but in this connection I think that the constitutional or general circulatory state is being lost sight of in our enthusiasm for local treatment. There are two drugs which were much used by our forefathers, and are still used by homeopaths that will frequently modify the severity and duration of the disease. They are aconite and belladonna. For some years I have been in the habit of prescribing drop doses of each of these drugs every hour or two, in the earlier stages of catarrhal affections, and have met with most favorable results. During the *grippe* epidemic of 1890 I had the opportunity of comparing the results of this treatment with that by salol and phenacetin, and found that, although less theatrical as regards the cessation of pain, they were more permanent and pleasanter in the relief of the catarrhal symptoms. Attention to the bowels is another important point, and the selection of the purgative is of equal importance. Too much scientific reasoning has obscured scientific observation in many cases, and the books give general directions to "move the bowels," but clinical observation will see better and speedier results from the administration of divided doses of either blue mass or calomel frequently repeated until the liver is slightly stimulated, than can be obtained from the use of salin or vegetable cathartics *ad nauseam*. Having been instructed to fear and dread the cumulative effects of drugs, and particularly the depressant effect of aconite, I exercise the precaution in patients of advanced age or in those having a feeble heart of prescribing at the same time large doses of strychnin, but I have practically never seen anything like depression follow small doses of aconite given in an acute catarrhal state, whereas I have seen cyanosis follow the administration of several of the antipyretics.

THE PHYSIOLOGICAL ACTION AND THERAPEUTIC USES OF YEAST NUCLEINIC ACID, WITH SPECIAL REFERENCE TO ITS EMPLOYMENT IN TUBERCULOSIS.

BY VICTOR C. VAUGHAN, PH.D., M.D.,
OF ANN ARBOR, MICH.;
PROFESSOR OF HYGIENE AND PHYSIOLOGICAL CHEMISTRY IN THE UNIVERSITY OF MICHIGAN, AND DIRECTOR OF THE HYGIENIC LABORATORY.

(Continued from page 264.)

TUBERCULOSIS.

THE principal object in writing this paper is to continue the record of my experience in the treatment of tuberculosis with yeast nucleinic acid. Before taking up the report of cases I wish to make some inquiry concerning the curability of tuberculosis.

The incorrect ideas of Virchow concerning the pathology of tuberculosis, and the equally erroneous clinical teaching of Niemeyer concerning the malignancy of this disease, have been so deeply impressed upon the profession that, although more than thirty years have passed since Villemin laid the foundations of correct knowledge by the discovery of the transmissibility of the disease from man to animal, and from animal to animal by inoculation, the shadow of the older teaching still falls upon us. If I may be permitted to modify and condense one of Cohnheim's statements on this point I should say: It happened fortunately that at the very time when Virchow was proclaiming the perfection of his teaching concerning the pathology of tuberculosis a discovery which was destined to prove his teaching erroneous was made in France.

Virchow attempted to make a sharp distinction between true tuberculosis and those processes in which caseation is, according to his teaching, due to inflammatory and hyperplastic processes. He taught that caseous pneumonia and scrofulous glands were not tubercular. The result of this teaching was that tuberculosis came to be regarded as a progressive process in which small malignant growths were formed, and which only exceptionally terminated otherwise than in death. Niemeyer founded his clinical teaching upon this pathology, and in doing so he employed statements more forcible in diction than true in fact, and these statements have not lost their influence upon the profession, although science has demonstrated their falsity. "The end of tuberculosis, as a rule, is death," is a statement which today largely determines the attitude of the medical profession towards the disease. "The greatest misfortune that can happen to one with phthisis is that he should become tubercular" is still practically repeated in much that is said about a "pretubercular" condition. The discovery of Villemin enabled investigators to demonstrate that the active virus in scrofulous glands, in granulation disease of the joints, in caries of the bones, and in caseous pneumonia is one and the same thing, and that susceptible animals inoculated with matter from any of these sources become tuberculous. With this evidence before him the pathologist repeated his studies from a vantage point and the researches of Schüppel, Buhl, Ziegler, Senftleben, Cohnheim, Baumgarten, Köster, Friedlander, and others in Germany, and of Ranvier, Cornil, Grancher, Charcot, Lépine, Thaon, and others in France, completely demolished the pathology of tuberculosis as taught by Virchow and demonstrated the existence of tubercular lesions in parts of the body once supposed to be free from such invasion, such as the conjunctiva, the cornea, the choroid, the iris, the skin, the muscles, the bones, and the blood vessels. Finally, the discovery by Koch of the specific cause of tuberculosis has given positive proof of the etiological unity of its various manifestations.

The erroneous teachings of Virchow as to the pathology of tuberculosis have lost their force for all except the few who professionally live in the distant past; but the clinical teaching founded upon this false pathology, and as especially exemplified in the writings of Niemeyer, is still a controlling factor in our treatment of this disease. We have been too slow to perceive that our advanced knowledge of the etiology and pathology of this disease has given us just cause for a more hopeful attitude toward it.

In 1882, Baumgarten[1] wrote in sum and substance as follows: "Tuberculosis is in and of itself not so bad a disease. We do not believe that it possesses, as a constant property, 'the considerable local malignancy' which Friedländer believes he must still unconditionally attribute to it. When we see individuals who as children had thickened, tuberculous cervical glands or tuberculous disease of the joints develop into the strongest and handsomest men; when we see people who in childhood had Pott's disease, which is always due to tuberculous caries of the vertebræ, live for years with this deformity, and reach advanced age; with such observations as these so frequently before us, we must conclude that tuberculosis is not so deadly as is usually supposed." . . . "The curability of phthisis pulmonalis was well known to the older pathologists. The distinguished Carswell wrote: 'In no other disease has pathological anatomy furnished more positive evidence of curability than it has for tuberculous disease of the lungs.' Under the dualistic theory, when a case recovered it was said to be one of simple inflammatory nature, and not tuberculous. However, since we know that caseous phthisis is tubercular, we must admit that tuberculosis is curable. The tendency to heal is much more evident in the 'true tuberculosis' of Virchow than it is in his caseous pneumonia. We will, therefore, come much nearer the truth if we take the oft-quoted saying of Niemeyer, 'The greatest misfortune which can happen to one with phthisis is that he should become tubercular,' and make it read as follows: 'The greatest misfortune which can happen to one with pulmonary tuberculosis is that he should become phthisical.'"

Tuberculosis, so long as it remains an unmixed infection, is not a deadly disease, and I believe it to be, in this stage, one of the most easily curable of the bacterial diseases. Except in the forms of acute miliary and meningeal tuberculosis, it is but seldom the direct cause of death. However, as soon as it becomes a mixed infection, and is something more than tuberculosis, it then takes rank as the most fatal of all the diseases now afflicting mankind. In combating this disease, there are two points of attack, and if the wisdom and skill of the profession be directed to these, the death rate from tuberculosis will be much reduced in the near future. The first and most important method of dealing with this disease consists of the application of preventive measures. With these, however, I have at this time nothing to do. The second, the one with which I am now concerned, consists of the treatment of the disease while it remains an unmixed infection. When this is done, tuberculosis will cease to be "the terror of the laity and the cross of the physician." In order to accomplish this work, however, we must put aside certain dogmas, which we have so long mistaken for facts that their shadows frighten us. We must be convinced that as an unmixed infection it is curable. We must be able to recognize the disease while it remains an unmixed infection. We must cease regarding certain conditions as evidence of the existence of an indefinite, imaginary, so-called "pretubercular" state, and must learn to look upon these conditions as proof of the actual existence of tuberculosis. I will now give attention to these points, and in so doing I will consider them quite apart from the claims which I may make for nuclein or any other agent employed for curative purposes.

Is tuberculosis a curable disease? If so, to what extent is it curable? What shall we understand by "the curability of tuberculosis"? Are tubercular deposits ever absorbed? Do such deposits ever wholly disappear and leave no trace of their former existence? May tissues once invaded by the bacillus tuberculosis regain histological continuity? Is there ever a *restitutio ad integrum*?

One-seventh of all men die of tuberculosis and one-third of all men have the disease. The first part of the preceding statement is shown to be true by the mortality statistics of all civilized countries. The second part of the same statement is shown to be true by the records of autopsies in various parts of the world. Massini[1] found evidence of tuberculosis as shown by scars, indurations, cheesy and chalky foci in eighty-nine out of 228 autopsies made upon persons who had died of diseases other than tuberculosis at the Basle Hospital. Müller[2] found in the Munich Pathological Institute that tuberculosis caused 29.4 per cent. of deaths in adults, and 30 per cent. in children, and that 11.8 per cent. more of the children had tuberculosis. Bollinger's[3] researches confirm these statements. Baumgarten[4] states that from one-fourth to one-third of all the bodies sectioned show tubercular lesions. Queyrat[5] found tuberculosis in 31.4 per cent. of the children examined. Lundonzy[6] reports that 30.4 per cent. of the children brought to autopsy are tuberculous. Babes[7] found tubercular deposits in one-half the children dying from all diseases at Bucharest. In 1887 he sectioned

ninty-three children, sixty-five of whom had tubercular glands. Haitnel[1] claims that one-third of the children examined at *L'hospice des Enfants assistés* show tubercular lesions. Simmonds, Schwer, and Boltz[2] state that autopsies at the Anatomical Institute at Kiel of 781 children, aged from one to five years, showed tubercular lesions in 230; of 228 between five and ten years, 78 were tubercular; of 162 between ten and fifteen years, 56. Wolff[3] states that autopsy reveals either recent or old tubercular lesions in from forty to fifty per cent. of adults and in from sixty to seventy per cent. of children; also that thirty per cent. of adults and forty per cent. of children have latent tuberculosis. Schlenker[4] found in 100 consecutive autopsies at Zurich 66 bodies tubercular; 35 of these had died of tuberculosis; in 4 others the disease was marked, but had not caused death; while in 27 it was latent and had not been suspected during life. In this examination no lesion was pronounced tubercular unless it was evident and characteristic to the unaided eye. He points out the fact that had the indurations been examined microscopically, the percentage of cases of latent tuberculosis would have been increased. According to Adossides[5] of 4815 bodies sectioned at Halle from 1882 to the middle of 1893, 1066 showed gross tubercular lesions.

These and other statistics of like import justify the assertion that about one-third of all men are, at some period of life, infected with tuberculosis. Now, if one-third be infected and one-seventh die of the disease, it must be that the difference between one-third and one-seventh, a little more than one-fifth, are tubercular but do not die of this disease. Of the sixty-three millions of people living in the United States in 1890, nine millions have died or will die of tuberculosis, while twenty-one millions have been, are, or will be infected with the bacillus tuberculosis. Does this not demonstrate that tuberculosis does not possess the malignancy attributed to it?

The fact that one may be infected with tuberculosis and such infection remain localized for many years is shown by the study of cases of lupus. Out of 27 cases of lupus studied by Doutrelepont[6] the infection spread and the patient died of tubercular meningitis in only one instance. Hasland found 6 cases of what he regarded as metastatic involvement of the internal organs in 53 cases of lupus, and Holm[1] observed 11 in 62.

The study of instances of accidental inoculation with the bacillus of tuberculosis in wounds, sometimes known as cadaver (Leichen) tuberculosis tends to similar results. It is true that the infection in these cases may extend to the internal organs, but often the disease remains a local infection and not infrequently a spontaneous cure occurs.

Verneuil[2] reports the case of an assistant who became inoculated at the root of a finger-nail while sectioning a tubercular body. Four or five days later a small point of suppuration appeared. Three years later the finger was amputated at the second phalanx and at the same time a tubercular abscess on the back of the hand was opened. Three years later still a bruise of the stump of the finger was followed by tubercular sequestration. Up to this time the internal organs had remained sound and subsequently the man died of spinal meningitis. Karg[3] reports the case of a physician who developed a wound tubercle on the thumb. For six years this remained without any signs of extension. Then the thumb became swollen and red and several tubercular abscesses developed along the lymphatics. These were opened and the bacillus found in the contents. Riehl[4] states that Dr. Karg inoculated himself in an interdigital fold. Two small tubercles were removed and found to contain bacilli. Kraske[5] observed a boy, who, after a surgical operation became infected from his tuberculous sister. The tuberculous growth was removed and the boy remained well. According to Tscherning[6] a servant inoculated her finger with the broken cuspidor of her tuberculous master. The tubercle at the point of inoculation and some swollen axillary glands were removed and in these the bacilli were found. The servant remained in good health. Lehmann[7] observed ten Jewish children with local tuberculosis after circumcision by a tuberculous rabbi. Three died of marasmus, three of tubercular meningitis, one of intercurrent diphtheria, and three recovered. Many other cases of wound tuberculosis have been reported and a valuable review of the subject has been written by Schmidt.[8] The study of these cases shows that inoculation with the bacillus tuberculosis does not always cause death, and that man is much less susceptible to the disease, when thus acquired, than are rabbits and guinea-pigs.

Further evidence that one infected with tuberculosis may recover from the disease is furnished in the observation of other forms of local tuberculosis. Tuberculous joints often heal, and the child afflicted in this way may develop into the most robust adult. König[1] says that coxitis may heal at any stage of the disease. Tubercular abscesses may disappear and leave scar tissue as the only evidence of their existence. Tubercular orchitis and tubercular pericarditis have been known to disappear. These evidences of the possibility of the healing of tissue once invaded with tubercles should encourage us, because in all cases tuberculosis begins as a local disease, and the tissue at first involved is only of microscopic extent. The germ is inhaled, and finds lodgment, and begins to multiply somewhere in the lung. The sooner the inoculation is recognized the greater are the chances of so improving the resistance of the tissue that extension of the infecting agent does not occur, and then it dies out or remains localized. I have stated that every case of tuberculosis begins as a local disease. The researches of Buhl and others have shown that this is true even in acute miliary tuberculosis and in tubercular meningitis. In these the systemic infection comes from a pre-existing tubercular focus. Friedlander[2] and others have described quite thoroughly the changes which take place in the spontaneous healing of local tuberculosis.

The evidence that tuberculosis of the peritoneum occasionally undergoes a spontaneous cure and frequently heals after laparotomy is no longer questionable.

Since the publication of the now classical paper by König[3] in 1884, on laparotomy in peritoneal tuberculosis, surgeons in every part of the world have resorted to this operation as a curative agent, with a fair degree of success. These cases have been collected and the results summed up by Phillips,[4] Lauser,[5] and others.

Adossides[6] has tabulated 405 laparotomies for tubercular peritonitis with thirteen per cent. of cures, counting as cured all those who lived two years or longer after operation.

It will be interesting to learn, so far as we are able, the histological changes involved in these cases of cure of tubercular peritonitis after operation. Is there a complete disappearance of the tubercles? Richelot[1] opened the abdominal cavity on account of strangulated hernia in a woman upon whom he had twice before performed laparotomy for tubercular peritonitis. The last operation for tuberculosis had been made one year before that for the hernia. He found the peritoneum perfectly smooth, of normal color, and free from adhesions. Knaggs[2] performed laparotomy for tuberculosis, and five and one-half years later operated on the same woman for hernia. At the second operation there was no trace of tuberculosis detectable, although at first the intestines, mesentery, and parietal peritoneum were thickly covered with tubercles. Clarke[3] reports a case in which an ovariotomy was made eighteen months after a laparotomy for tubercular peritonitis, and the second operation showed that the tubercles had wholly disappeared. Similar cases with similar findings have been reported by Schede, Winiwater, Ahlfeld, Hirschberg, Schmalfuss, Tait, Feldmann, Terillon, Esmarch and Werth (see monograph by Adossides).

These observations demonstrate not only that tubercular peritonitis may be cured by laparotomy, but that the cure may mean a complete *restitutio ad integrum*.

The following experiments bear upon this point: On December 31, 1895, we inoculated three full-grown rabbits intra-abdominally with a pure culture of the bacillus tuberculosis. No. 1 was employed as a control, and received no treatment of any kind. It died May 25, 1896. The peritoneum, omentum, liver, and spleen were tuberculous. There was also a large tubercular abscess in the abdominal wall at the point of inoculation.

No. 2 was placed in the holder January 25, 1896, and the abdominal cavity opened. In the wall at the place of inoculation there was a tubercular induration as large as a nickel. In the mesenteric fold of the colon there was a tubercle as large as a pin-head and many smaller ones. The omentum was filled with small nodules, and the border of the liver was dotted with pin-point tubercles. After noting these facts, the abdomen was closed and nothing more was done to this animal until July 24, 1896, when it was killed. What had been a tubercular induration in the wall was at the autopsy only a lump of yellow fat. No sign of tubercle could be found in it. The liver was perfectly sound. There were heavy deposits of fat of a deep yellow color in the omentum and mesentery, and in these the tubercles observed at the time of the laparotomy were found. These nodules had not increased in size, but they contained a caseous center in which tubercle bacilli, which stained normally, were found.

[3] *Ibid.*

No. 3 had its abdominal cavity opened January 25, 1896. There was an induration in the wall at the point of inoculation similar in size and appearance to that observed in No. 2. The mesentery and omentum were filled with nodules the size of flaxseed and the border of the liver dotted with fine tubercles. One nodule was cut from the omentum and examined for bacilli, which were abundantly present. The abdomen was closed, and 45 c.c. of a one-half per cent. solution of nucleinic acid was injected into the jugular vein. Nothing further was done to this animal until July 24, 1896, when it was killed. Not the slightest evidence of tubercle could be found anywhere. The induration in the wall had wholly disappeared and the mesentery and omentum were perfectly smooth. The deposits of yellowish fat observed in No. 2 were not found.

The following details will show that the skin and muscles may also regain histological continuity after tubercular invasion. November 18, 1895, two rabbits, which may be designated as A and B, were inoculated intra-abdominally with tuberculous sputum. The weight of A was 1552 and that of B 1402 grams. On December 6, 1895, A died. There was a caseous infiltration extending for one and one-half inches longitudinally and one-fourth inch transversely under the skin of the abdomen. The muscles of the abdomen were infiltrated with a creamy, semi-solid exudate, in which the diplococcus pneumoniæ, in great numbers, and the bacillus tuberculosis, in small numbers, were found. There was some effusion in the peritoneal cavity, and in this also both the above-mentioned germs were present. Death was due to the septicemia induced by the diplococcus. At this time B showed a suppurating sore two inches in length and one-fourth inch broad on the abdomen, and a round ulcer three-fourths of an inch in diameter and extending deep into the muscles on the right thigh. Tubercle bacilli were repeatedly found in the pus from each of these sores. December 6, 1895, 50 c.c. of a one per cent. solution of nucleinic acid was injected into the jugular vein and the next day 15 c.c. more was injected into the vein of the ear. On December 7 B weighed 1394 grams, on December 14, 1480, and on December 21, 1592. On December 27, B was found to be losing in weight, falling to 1542 grams. At this time the sore on the abdomen had healed over, but a nodule had appeared at the point of inoculation and had grown to the size of a filbert. The sore on the hip was still discharging, although it had decreased very much in size. On December 27, 1895, B received hypodermically about the nodule on the abdomen 30 c.c. of the one per cent. solution, and two days later 40 c.c. more. After this B received no further treatment, but continued to grow fat and strong. On July 23, 1896, B was killed; weight at that time was 2030 grams. There was some adhesion of the skin to the muscles over the abdomen where the sore had been, but nothing more. The hard nodules had wholly disappeared. All internal organs were in perfectly normal condition. The ulcer on the hip had wholly disappeared and there had been complete reconstruction of the injured tissues. There was not even a scar to mark the place of the former lesion.

I have brought forward these observations on the rabbits at this time not for the purpose of making any claims for nuclein, but in order to show that there may be a *restitutio ad integrum* in tissue after tubercular invasion. For my present purpose it matters not what be the nature of the agent that brings about the restitution.

Many theories have been advanced to explain the curative effect of laparotomy on tubercular peritonitis. It has been attributed to the influence of the light, which reaches the peritoneum during the operation (Lauenstein), to the entrance of air (Mosetig-Moorof), to mechanical irritation and the presence of air (Caspersohn), to the bacterium termo, which is supposed to enter the cavity with the air (Cantani), to a digestive action of the peritoneum, that is assumed to be called into action by ths operation (Sänger), to a suction action, "aufsaugende kraft" of the peritoneum, due to the relief of pressure (Fritsch), to the oxygen of the air (Braatz), to improved resorption (Lindner), to inflammatory adhesions (König, Breisky, Hartman, and Aldibert), to a connective tissue reaction (Phillips), to improved circulatory and respirating action, and to relief of the autointoxication (Vierordt), and to the use of disinfectants used in the operation and sometimes in washing out the cavity (Preindlsberger and Ceccherelli). However, the explanation suggested by Kischenski[1] that the cure is due to the leucocytosis which follows the operation is the most reasonable. Adossides accepts this explanation and sensibly adds that the action of the leucocytes is favored by (1) the relatively small number of bacilli present, and (2) the great extent of the peritoneal membrane and its great vascularity.

Tubercular peritonitis has been cured not only by surgical means, but under medicinal treatment also. Such cases have been reported by Bouilard, Vierordt, Anderson, Comby, Fagge, and others.

Cases of tubercular meningitis terminating in recovery have been reported, but from the nature of the disease it is difficult to furnish positive evidence to this effect. However, such able diagnosticians as Rilliet and Trosseau have reported cures. I have carefully studied the monograph by Zwicke[1] on this subject, and must conclude that he does not supply convincing proof of the correctness of his diagnosis in the case of cure reported by himself.

---

[1] *Centralblatt für Chirurgie*, 1893.

The researches of Orth,[2] Fraenkel,[3] and Prognbinsky[4] have demonstrated that tuberculosis may be located primarily and exclusively in the larynx, and Schmidt[5] claims to have cured five cases of this disease by tracheotomy. He attributes the curative action to the rest given the larynx and to the more direct action of the oxygen of the air. Glöckner[6] has reported two cases treated by tracheotomy without benefit, but in both of these the lungs were extensively involved and the ulceration of the larynx was probably secondary; certainly the disease was not confined to the larynx. Krause[7] has claimed success in the treatment of laryngeal tuberculosis by his method, with lactic acid, and his observations have been confirmed by von Schroetter,[8] Keimer,[9] Heryny,[10] Jellinick,[11] and others. Like good results are claimed for iodoform by Beschorner,[12] Schultzer,[13] and others.

In regard to the cure of pulmonary tuberculosis, either spontaneously or under climatic or medicinal treatment, there is much information to be found in medical literature, but it can not be so positive as that given concerning peritoneal tuberculosis. If there be histological restoration there can be no evidence after death of the existence of the disease during life. Scars and chalky deposits are frequently observed, and the fact that these contain tubercle bacilli demonstrates the former existence of the disease in an active form. Carswell[14] states, as has already been quoted, "that pathological anatomy has probably not given such positive proof of the curability of any other disease as it has of phthisis." Weber[15] says: "It seems to me impossible for any one acquainted with the literature of the subject to doubt the curability of phthisis." Rühle[1] asserts that tuberculous processes in the lungs may heal.

Green[2] says: "It lies in the very nature of the case that there can be no absolute cure, no *restitutio ad integrum*, and the very best that can happen is the formation of a scar or of a chalky deposit."

"One frequently has the opportunity of seeing these healed foci in various stages; sometimes as scars, again as connective tissue nodules, or as cavities filled with chalky concretions. The size of these cavities varies from that of a hemp seed to that of a hazelnut. Generally the remainder of the lung is in a normal condition. These healed places are generally found in the apices, where tuberculosis most frequently begins. They lie near the surface; the apex is more or less contracted; the pleura pulmonalis is thickened and more or less adherent to the pleura costalis. To the finger these points feel like hard lumps. The interior of the nodule consists of a well encapsuled mass of variable consistency depending upon the length of continuance of the healing process. The center is hard, generally calcified, while the periphery is softer, incompletely calcified."

Green has examined a number of these healed cavities microscopically and in some the bacilli were detected, while in others the result was negative. Dejerine[3] has made a similar study with like results. He also inoculated guinea-pigs with the wholly calcified material and failed to induce tuberculosis. Kurlow[4] obtained the following results from his inoculations:

1. Using scar nodules in which no bacilli could be found; two inoculations; both negative.

2. Using completely calcified nodules in which no bacilli could be found; four inoculations; all negative.

3. With caseo-chalky nodules about which no tubercles could be found. In many of these nodules no bacilli could be detected; twelve inoculations; all the animals became tuberculous.

4. With caseo-chalky material about which tubercles were found; seven inoculations with positive results in all.

Nauwerk,[5] Demme,[6] and others, have given the clinical histories of cases of recovery from pulmonary tuberculosis with death from some other disease and the findings at autopsy.

[6] "Jahresbericht über die Thatigkeit des Jennerschen Kinderhospital in Bern," 1884.

Wolff and Saugmann[1] have given us valuable information concerning the possible cure of pulmonary tuberculosis. In 1862 Brehmer began the treatment of tuberculosis in his hospital at Görbersdorf. In 1890 Wolff and Saugmann sought out many of the earlier cases treated by Brehmer, and reported upon their condition. The number found and studied was 142. In some of these the evidence of the previous existence of the disease and its arrest cannot be doubted. One of these is reported as follows: In 1876, a woman entered Brehmer's hospital with infiltration of the right lung to the third rib, and a less marked infiltration over the same area of the left lung. She had fever and night sweats, and was reduced in flesh. She remained in the institution thirteen months, and was dismissed "cured." Fourteen years later she was operated upon for myomata uteri and died. A few days before death her lungs were carefully examined, and the only evidence of disease that could be found was a slight prolongation of the expiratory sound over the upper right lung. Section showed a cicatricial contraction, with a circumference of about 4 cm. in the right apex; otherwise no abnormality could be found in the lungs and no tuberculosis in any part of the body. In microscopical sections of the scar tissue tubercle bacilli, which stained well, were found. The authors are certainly justified in the conclusion drawn from the case. Considering the severity of the case when it came under treatment, fourteen years before, the cure must be regarded as ideal, but, nevertheless, it was not absolute, because the bacilli remained and, as indicated by the tinctorial reaction, retained their vitality, and in this respect the patient showed a condition no more serious than that exhibited by "one-half, or at least one-third, the bodies that reach the autopsy table."

These authors conclude that at least eight per cent. of those treated at Görbersdorf from 1862 to 1891 were permanently cured.

I have gone into the question of the curability of tuberculosis thus specifically (and I might say that the evidence on each point might be confirmed more fully did space and time permit) because I believe that the present attitude of the profession in general toward this disease is radically wrong and harmful. I believe that I am right in saying that the average physician does not strive to recognize this disease as early as is possible, but that he wilfully disregards all evidence of its existence until, in the majority of instances, it is altogether too late. I shall have something to say concerning the means of an early diagnosis in another part of this paper.

I will now proceed to state the results obtained in the treatment of tuberculosis with yeast nucleinic acid. In doing this I will make the reports of cases as short as is possible, and at the same time consistent with clearness. In order to avoid repetition, I may state here that in all of the seventy-five cases reported the tubercle bacilli were found; and in all of the urinary cases guinea-pigs were inoculated and tuberculosis developed, in order to be certain that I had not mistaken the smegma bacillus for that of tuberculosis. No case is reported in this list which first came under observation later than December, 1895.

(To be continued.)

CLINICAL MEMORANDA.

A CASE OF INTRAUTERINE HYDROCEPHALUS OF UNUSUAL SIZE; EVACUATION OF THE FLUID THROUGH THE SPINAL CANAL, FOLLOWED BY EASY DELIVERY OF THE HEAD.

BY IRA G. STONE, M.D.,
OF MEAD, NEB.

ON the morning of December 30, 1895, I was called in consultation to see a case of difficult labor. Arriving at 5.30 o'clock, I obtained the following history: Mrs. D., of Irish extraction, rather under medium size, with small bones, but pelvis of fair capacity. Two normal confinements preceded the present one. At this confinement she was taken in labor on the evening of December 29th, after a normal gestation, and at 2 o'clock on the morning of December 30th a breech delivery of the fetal body occurred, but the head could not be induced to descend. On examination, I found the fetus to be of rather small size, poorly nourished, and with contractions of both lower extremities (double talipes equino varus). The arms were delivered, but the shoulders remained well up in the lower vaginal tract, the right resting under the pubes and the left low down in the sacral concavity. In this condition the patient had remained from 2 to 5.30 o'clock, A.M. By making strong traction on the fetal body, I succeeded in stretching the neck sufficiently to bring the shoulders down so that an examination with the finger, though difficult, could be made up to the base of the skull. By withdrawing and reinserting the finger at various points, I finally succeeded in carrying the examination sufficiently far to satisfy myself that the retention was due to an enlargement of the fetal head.

On examining the surface of the abdomen of the patient, the uterus was found to extend about two inches above the umbilicus, and to be filled with a semi-solid substance, in which nothing definite could be outlined. Its contour was nearly round, and pressure at all points over the uterine surface yielded the same degree of resistance, with no well defined hard points or projections.

The necessity of relieving the woman at the earliest possible moment was imperative, as the expulsive efforts on the part of the uterus had become very feeble, and her condition was that of extreme exhaustion. Of the several methods adopted for tapping the fluid contained in the head, I chose the one suggested by Van Huevel, and first performed by Tarnier in 1876—that is, by reaching the accumulated fluid by way of the spinal canal. My reasons for adopting this method were based on the following facts: (1) Owing to the large size of the fetal head, it could not be brought low enough in the pelvic cavity to be easily reached alongside the neck. (2) To reach the base of the skull between the vaginal walls and the side of the trunk and neck of the child, which crowded the vagina to its utmost capacity, would have been very difficult, to say the least. (3) The danger of wounding the maternal tissues with either a cutting or perforating instrument, and the subsequent possibility of the absorption of septic material, was to be considered as of no small consequence. (4) The absence of the proper instruments, which is so common to the practitioner in remote districts.

---

[1] "Ueber Dauerende Heilung der Lungentuberkulose," Wiesbaden, 1891.

On the other hand, the advantages of tapping through the spinal canal, in this case at least, were: (1) The ease with which the fluid could be reached through this hollow tube, protected as it is on every side by the hard resisting walls formed by the vertebræ. (2) The absolute safety to the maternal tissues, they not coming in contact with cutting or perforating instruments. (3) The few and every-day instruments required to do the operation, and (4) because the operation could be performed directly under the supervision of the operator's eye.

After deciding, for the above reasons, to reach the fluid through the spinal canal, I proceeded as follows: Placing the woman in an easy position, with the fetal back well exposed and easily accessible, I made a transverse incision, about two inches long, across the spinal column of the child, as near the external parts of the mother as convenient. This incision was carried down between the spinous processes, and was located below the center of the scapula. Then an incision was made parallel with the spinal column, and of about the same length as the first, directly over the ends of the spinous processes, and carried downward. After making the incision, the flaps were turned back on each side down to the spinal column, and then the posterior segment of one of the dorsal vertebra was removed to facilitate the entrance of the catheter. Having with me only a soft rubber catheter, I found it too flexible to force its way through the canal, so withdrew it and placed the end of a uterine sound through its eye, and had no difficulty in passing it on into the fetal head, and as soon as the catheter entered the head a flow of almost transparent fluid occurred, and continued until sixty-four ounces had been drained off. About this time uterine contractions became stronger, and by moderate traction on the fetal trunk, aided by suprapubic pressure, the head was delivered, still containing a considerable quantity of fluid that had not passed off through the catheter. The fluid had a specific gravity of 1006 at the body temperature, and well-marked alkalin reaction. The placenta was delivered in due time, and the patient made an uneventful recovery.

In reporting this case, I have two objects in view. The first is to point out the advantage of entering the cranial cavity by the way of the spinal canal over that of tapping through some point at the base of the skull, gaining access thereto by way of the vagina. The second point which I wish to bring out does not necessarily belong in this report, yet I wish to present it, from the fact that the condition was present in this case, and, taken into consideration with other evidence, aided me in making a diagnosis of intrauterine hydrocephalus. The proposition is that congenital contractures of the extremities are due to an intrauterine irritation located somewhere in the cerebrospinal tract.

A CASE OF EARLY CEREBRAL SYPHILIS.[1]

By DOUGLASS W. MONTGOMERY, M.D.,
OF SAN FRANCISCO, CAL.;
PROFESSOR OF DISEASES OF THE SKIN, MEDICAL DEPARTMENT OF THE UNIVERSITY OF CALIFORNIA.

THE idea used to be prevalent that the syphilitic virus first expends its energy on the skin and mucous membranes, and that the deep internal organs are not affected until far later in the course of the disease. This is notably not the case, however, as far as the brain is concerned, and now cerebral symptoms are among the well recognized phenomena of early secondary syphilis. The following case is illustrative of this proposition:

On November 24, 1891, Dr. Louis Bazet sent me a patient, twenty-two years of age, who had a discrete papular eruption with excoriated tops on the face and scalp, a lenticular papular rash on the lower limbs, tenderness and induration of the left epitrochlear lymphatic gland, and tenderness over the situation of the right, enlargement of the posterior cervical lymphatics, sore throat, tenderness on deep pressure over the sternum, and a sallow complexion. Dr. Bazet informed me that the patient had left the Eastern States the month before to come to San Francisco, and that a sore had developed on the foreskin during the journey, which the patient had repeatedly cauterized with nitrate of silver. He evidently belonged to that class, the *jeunesse argentée*, who know altogether too much about the use of nitrate of silver.

When he came under Dr. Bazet's care, about November 1, 1891, he was in a bad condition. The temperature had run up to 103° F., the sore on the foreskin necessitated circumcision, and several inflamed and suppurating buboes had to be enucleated from each groin. The unfortunate course of the disease up to this point may have been due to the irritation caused by the previously-mentioned repeated and insufficient self-inflicted cauterizations. There being no doubt that he was suffering from syphilis, a corrosive sublimate lotion was prescribed for the rash on the face and scalp, and protiodid of mercury pills were given internally.

I did not see the patient again until about nine months later, in September, 1892, when he called on me at Dr. Bazet's instance, complaining of severe pain in the occiput. The epitrochlear and posterior cervical glands were no longer demonstrable, and the rash had disappeared, but the patient was anemic. The urine was alkalin, but otherwise normal. In the intervening time he had been undergoing treatment faithfully, but his habits with regard to being out at night, smoking cigarettes, etc., had remained irregular. He was working in a badly ventilated office, but not by any means too hard. The headache was ascribed to the anemia, and the anemia to the irregular habits, the confinement in the office, and possibly also to the mercurials which he had been taking. The cessation of specific treatment, the taking of the elixir of iron, quinin, and strychnin, and a holiday, were advised.

---

[1] Read before the San Francisco County Medical Society, December 8, 1896.

He went to Monterey, and complained bitterly while there of what he thought were piles, but which were afterward found to be condylomata. In a short time he returned to San Francisco, still suffering from severe headache. While walking under a hot sun he suddenly complained of an intense pain in the head, and, a few days afterward, after being again exposed, it was noticed that his face flushed in a peculiar way. On the afternoon of the following day he had a "fit," tonic and clonic, with biting of the tongue and loss of consciousness, and during its progress attempted to jump out of a window. When seen about an hour after the attack he was sitting on a sofa, dazed and restless. His heart was beating rapidly, his pupils were equal, there was no paralysis, and his tongue protruded straight. This was on October 5, 1892, a little over one year after the sore was acquired.

The important question now before us was whether we should consider the epileptic seizure as a symptom of syphilis, for, in this case it required energetic antisyphilitic treatment. Viewing it from the standpoint of epilepsy alone, it is doubtful if it would have been right to ascribe it to the specific disease. Idiopathic epilepsy commences early in life, and this man was only about twenty-three years of age. If it had occurred for the first time later in life the intrinsic evidence of the convulsion being a symptom of syphilis would have been much stronger. Fournier has said that when epilepsy first appears at from thirty to thirty-five and forty years of age, in the very large majority of cases it is syphilitic. Seligmüller places the age much younger, and asserts that when an epilepsy commences in an apparently healthy individual past twenty years of age it is decidedly indicative of the presence of constitutional syphilis. This point of the intrinsic value as a symptom of syphilis of an epilepsy that commences in adult life is not by any means settled, however, and Mendel has expressed himself as at any rate against any such extreme view as that of Seligmüller.[1]

Viewing the convulsion in the light of all the facts, however, we were fully justified in taking this to be an epilepsy due to syphilis. It is now well known that although well-marked cases of syphilis of the brain cannot be said to be of frequent occurrence, when one takes into account the vast number of people suffering from this disease, yet, when cerebral syphilis does occur, it comes on far more frequently in the early than in the late course of the disease. Lang recently quoted a list of 168 cases of cerebral syphilis collected by Charles Mauriac, of which seventy-two, or 42 6-7 per cent. began during the first two years of the disease.[1] Furthermore, cerebral syphilis frequently first manifests itself by a prolonged and severe headache, followed by an epileptic seizure. We, therefore, had a young man in the early secondary stage of syphilis, with condylomata of the anus, suffering for the first time in his life from an epileptic fit, which had been preceded by a severe prolonged headache. The predisposition to this manifestation of syphilis brought on by the patient's habits ought also to be taken into account here, for the localization of the disease in the nervous centers, and especially in the brain, occurs chiefly in two classes of individuals—those who are fagged by mental work and worry, and those who are jaded with pleasure,[2] and he belonged to the latter class.

The evidence, therefore, was overwhelmingly in favor of the affection being syphilitic, with very few chances that it was not. He was immediately put on inunctions of mercurial ointment, and iodid of potash was administered internally. There was constant pain and tenderness of the crown of the head after the epileptic seizure, and this and the condylomata around the anus were the only symptoms the patient complained of. He was drowsy and taciturn, and his face had a mask-like appearance. He soon developed a decided fetor of the breath from the mercury, although every precaution was taken to keep his mouth clean. The inunctions were then stopped, the iodid of potash was increased up to forty-five grains a day, and Zittmann's decoction and cascara sagrada were also given to combat an obstinate constipation, which had come on after the epileptic attack, and which lasted till the severer nervous symptoms disappeared.

From November 3d to November 7th he had a slight rise of temperature of from a degree to a degree and a half every afternoon. Also, about this time, a paresis of the right side of the face, and then of the right upper and lower extremities, developed, but so slowly as to make it impossible to exactly fix the date of its supervention. No loss of sensation of any kind, either of pain, touch, temperature, or locality could be made out, but these observations were not exact, because of the patient's still stupid condition. He had no ataxia nor loss of patellar tendon reflex. He could not whistle, but he could always pronounce the labials well. He became decidedly aphasic, and very irritable when he could not remember names. He also became hypersensitive to both light and sound, and the barking of a neighbor's dog bothered him a great deal. The photophobia and the irritability of the auditory nerves seemed to be bilateral. These were the only ocular or auditory symptoms observed. About the middle of November, under the continued use of iodid of potash, 180 grains a day, he became much brighter, and the irritability to light and sound became noticeably less. The paresis of the right side of the face and of the right arm still continued, and the right thumb lay in the palm of the hand. One night toward the end of the month he wetted the bed, but we were inclined to consider this an accident rather than a symptom. During the next few weeks he improved steadily, both in regard to the paresis and the general symptoms, and about January 1, 1892, he felt well enough to take a trip to the southern part of the State. He still continued the iodid of potash in full doses, however, up to the middle of January. He then gave up taking medicine, and resumed the use of cigarettes, coffee, etc.

[1] *Vorlesungen über Pathologie und Therapie der Syphilis*, von Prof. Dr. Edward Lang, p. 518.

[2] Fournier, *Traitement de la Syphilis*, p. 99.

The fact that the brain symptoms began first with prolonged headache, followed by an epileptic attack and a subsequent hemiplegia, and that the onset of this hemiplegia was so insidious that the date of it could not be determined, and also that the paralysis, although distinct, was not at all profound, as well as the great variety of the nervous symptoms all corresponded with what is known to take place in syphilis of the brain. In all probability it was a syphilitic endarteritis of the left Sylvian artery, which narrowed the caliber of the blood vessel so that it did not carry sufficient blood to the left motor area. At first it gave rise to a headache from irregularity of circulation in the meninges, then epilepsy, and finally paresis throughout its wide area of distribution. It did not give rise to complete blocking and thrombosis of the vessel.

When the patient came back to San Francisco, after being away a month, he walked with a firm step, talked with precision and with his usual speed, and could write well. He went back to business immediately, but found he could not add figures as quickly as before; this was the only difficulty under which he labored. In a few days he called on me again, complaining of a severe "cold," and of muscular rheumatism in the right shoulder. Exactly two weeks after his return he was again confined to bed, suffering from coarse and fine tremors of both upper and lower extremities, and of the tongue. The most marked tremors were those of the hands. At first he was not able to write at all; two days later he could do so, but badly. The right arm was still not as strong as the left, and he said that it had never fully recovered from the first attack. He could not detect any difference in strength between his lower extremities. It was difficult to say if the face had returned to the normal as regards the paresis. We thought it had, for a drawing of the mouth to the left when he laughed was probably an inherited facial peculiarity and not a symptom. The sensations and reflexes were normal. His mind appeared to be clear, and his speech, except for some slight thickness in articulation, was normal. He said he had caught cold from sitting with his back to an open window. These tremors were not from mercury, as he had not been taking that drug for a long time. He was again put on iodid of potash, and went south, stopping a short time for treatment at Arkansas Hot Springs, and from there returned to the East.

I again saw the patient for a few minutes on the street on May 23, 1894, that is, over nineteen months after the epileptic attack. He had not done any work since his last illness, but had quietly settled down on the mother lode, and appeared to be working his claim quite successfully. He had just returned from the Eastern States, and was on his way to buy his ticket back again. He shortly afterward went to Paris for no known reason. This aimless wandering is a noticeable feature in some cerebral affections attributed to syphilis, and may have been a symptom of continued irritability of the brain in this case.[1]

The patient was married December 5, 1895, and his wife had a spontaneous miscarriage in May, 1896, at the second month of pregnancy. This was a very suspicious circumstance, in view of the fact that miscarriage is such a well recognized symptom of syphilis. It will be noticed that this miscarriage took place four and one-half years after the appearance of the man's primary lesion, and that during that time he had undergone a rigorous and prolonged course of treatment under Dr. Bazet and myself, another at Arkansas Hot Springs, where they have the reputation of not sparing medicine, and still another under a well-known specialist at the East.

HOSPITAL REPORT.

RESULTS OF FIVE MONTHS' TREATMENT OF DIPHTHERIA WITH ANTITOXIN AT THE NEW YORK FOUNDLING ASYLUM.

By J. LEWIS SMITH, M.D.,
OF NEW YORK;
VISITING PHYSICIAN TO THE ASYLUM.

The New York Foundling Asylum furnishes unusual facilities for observing diphtheria and the effect of its treatment. The number of infants cared for is necessarily much larger than can be accommodated in the wards, and a considerable number are therefore farmed out in tenement houses, and if they are taken sick are returned to the asylum.

The present house physician, Dr. J. D. Voorhees, has furnished the following table, showing the number of cases of diphtheria, and of deaths therefrom, occurring in the asylum during each of the seven years ending with December 1st:

Years.	1890	1891	1892	1893	1894	1895	1896
Cases.	71	67	60	123	133	94	147
Deaths.	36	35	23	34	32	43	18

During the five months ending December 1, 1896, the effect of the antitoxin treatment was carefully observed by the visiting physicians and house staff, with such attention to details as would be likely to increase the efficacy of the serum therapy. It was soon found that the injurious or negative results of the antitoxin treatment in the asylum during the first year of its use had been due to causes which might be avoided. The serum first used was prepared by a French company, in much too brief a period and without the proper testing, and of course proved unsatisfactory. The serum obtained from the New York Board of Health was found to be pure, efficacious, and in every way satisfactory. It is now used in the asylum to the exclusion of all other serums, and those who have witnessed its effects have often been

---

[4] See instances of aimless wandering in general paralysis of the insane given by Ch. Berger, *Arch. clin. de Bordeaux*, IV. I, p. 25; 1895.

astonished, that a disease ordinarily so fatal, and the initial symptoms of which appeared often to indicate a severe type of the malady, became so mild in twenty-four hours after the first injection.

It will aid in the investigation of the therapeutic value of diphtheria antitoxin to recall to mind the nature of the disease. The theory has long been accepted that it is produced by a bacillus which does not enter the general system, but generates a toxin which is readily absorbed and acts as a speedy and deadly poison. The virulence of this toxin is the cause of death except in those cases in which a pseudo-membrane clogs the air-passages. It is believed by the advocates of the antitoxin treatment that the immunity which antitoxin produces checks further exudation, causes the exudate to shrivel and peel off, and arrests the further progress of the disease. Obviously, therefore, in order to be most effectual the antitoxin should be used as early as possible on the first day of the appearance of symptoms. The following have been the approximate quantities used in the asylum for the first injection, and it has been only in exceptional cases that a second was required on the following day: From six to eighteen months, 750 units; from eighteen months to three years, 1000 to 2500 units; above three years, 2000 to 2500 units.

The following table gives the number of cases treated and the result, during the five months ending with December 1, 1896. Bacteriologic and microscopic examination of every case was made by the resident physician, and independently by the Bacteriological Department of the Board of Health. The Klebs-Löffler bacillus was found in every instance:

	Total Cases.	Died.
July	10	1
August	6	0
September	5	0
October	19	1
November	25	1

The fatal case in July was that of an infant of seven months, admitted in a nearly dying state. It had double pneumonia, and a diphtheritic exudate extending from the tip of the nose nearly to the lungs. Slight as was the chance of benefiting the patient, 750 units of antitoxin was injected, but without any appreciable effect in staying the fatal result. The fatal case occurring in October was that of a female bottle-fed child having enterocolitis of three weeks' duration. She was entrusted to a family in a tenement house September 15, 1896, but remained in a weak and wasted state, and was returned to the asylum October 16th, when she was found to have gangrenous inflammation of the throat, uvula, and tonsils. Her extremities were cool, a bed sore had appeared in the sacral region, her temperature was 101° F., and a culture showed the presence of the Klebs-Löffler bacillus. Without any expectation of benefit, since the infant was nearly moribund, an injection of 1500 units of antitoxin was given, but without effect, death taking place two days later.

The following is the history of the fatal case occurring in November: Mary X., eight months old, was born in the maternity service of the asylum. She was wet-nursed by her mother, and apparently received sufficient breast-milk. The record of November 1st stated that she was pallid, in poor general health, and had had a cough with some acceleration of respiration for three or four days. The temperature was 104.5° F. In the upper lobes of both lungs were heard the râles of pneumonia. On November 5th, dulness on percussion was distinct over the lower two-thirds of the right lung. The pulmonary signs continued, although with apparently some abatement, and on November 12th the temperature was nearly normal. The breath was offensive, but there was no nasal discharge. On November 15th and 16th, two small white points were observed on the uvula, and a culture from them demonstrated the presence of the Klebs-Löffler bacillus. One thousand units of antitoxin was injected. At this time the temperature was 101°F., and both sides of the neck exhibited swollen glands. Death occurred on the following day. At the autopsy the right pleural cavity was found to contain three ounces of thick encapsulated pus lying over the liver and compressing the right lower pulmonary lobe. The right upper and middle lobes also contained small encapsulated collections of pus. Broncho-pneumonia was present in the left lower lobe, and the cervical, axillary, and bronchial glands had become hyperplastic. The other organs exhibited no notable change, apart from the emaciation.

It is seen that these three patients were sick, with little prospect of recovery, before the commencement of diphtheria. Of the 65 diphtheritic cases embraced in the statistics of the five months, 12 had symptoms of croup, either in its incipiency or more or less developed. Nine of these recovered under the antitoxin treatment without intubation, while the remaining 3 required intubation only as an auxiliary measure. In these nine cases the croup was apparently checked by the action of the antitoxin. One of the three patients had the following unusual but not unique history, which shows that notwithstanding the efficacy of the serum treatment and the power which it exerts in arresting croup, intubation is sometimes necessary as an adjuvant: Joseph, aged three years, with a pseudo-membrane over each tonsil, began to have embarrassment of respiration and the characteristic harsh cough of croup on November 13th. Antitoxin (2000 units) was at once given. On November 14th, the antitoxic injection not having given relief, the child was intubated and 1500 additional units injected. On November 16th, the tube was removed so as to test the respiration, but the dyspnea necessitated its immediate replacement. The lividity and dyspnea occurred each time the tube was removed during the next three weeks. It was taken out six times, the lime salts, membranous *débris*, and mucopus removed, and then it was immediately reintroduced. After the third week it was no longer needed.

The effect of the antitoxin when the diphtheritic exudation is located in unusual situations is interesting and instructive, as showing its potency and far-reaching influence. Thus, on August 18, 1896, W. M., aged four months, was presented for treatment, his right eye being badly inflamed and both lids swollen. The diagnosis of purulent conjunctivitis was made. A pseudo-membrane covered the under surface of both eyelids, but the examination of the corneæ was negative. The Klebs-Löffler bacillus was found in the secretions. A drop of atropin was applied to the right eye morning and evening, a compress wetted in a saturated solution of boric acid was constantly applied over the lids, and an injection of 750 units of antitoxin was given in the connective tissue. The eye was clearing rapidly by October 22d, and recovery was soon complete. In two other cases the same quick recovery occurred, one being in a patient upon whom circumcision had been performed, the inflamed surface being covered with a diphtheritic exudate, and the other in a patient having a vaginal ulceration. In both wounds the Klebs-Löffler bacillus was found, and one injection of the antitoxin sufficed to effect a cure.

Delafield and Prudden, in the fourth edition of their treatise on "Pathological Anatomy" (page 149), say: "There is a considerable number of very important inflammatory lesions, closely allied in their character, and commonly, though not always, associated with suppuration which are due to the presence and growth in the body of the spheroidal bacteria or cocci known as staphylococcus pyogenes and streptococcus pyogenes." These forms of cocci, associated with the Klebs-Löffler bacilli, have been present in a majority of cases of diphtheria which I have examined in the Foundling Asylum, and I think that members of the medical staff who have made a greater number of microscopic examinations than myself, have observed the same frequency, or even preponderance, of the cocci, the infection thus being a mixed one. In some cases the diphtheria bacillus occurred alone. The presence of these cocci doubtless aggravates the diphtheritic process unless the latter can be checked in the beginning, before the inflammation produced by the Klebs-Löffler bacillus becomes fully established. Hence, physicians of the Foundling Asylum employ from the first, in order to destroy cocci upon the nasal and pharyngeal surfaces, such applications as a saturated solution of boric acid, or one of the combinations given in the MEDICAL NEWS for August 29, 1896.

Amid all the changes which have occurred in the therapeutics of diphtheria during the last fifty years, the tincture of the chlorid of iron has continued in common use as a tonic and astringent. Recently the syrup of pineapple has been used as an eligible vehicle for the iron in the following formula:

℞—Tinct. ferri chlorid, ... ʒ ii
Syr. ananassæ sativæ . . . . ℥ iii
Glycerin . . . . . . ℥ ss.
Dose: One teaspoonful to a child of three to five years.

The iron has been employed in most of the diphtheria cases which received the antitoxin. No one, it seems to me, can peruse the foregoing statistics, especially if he has had an opportunity to observe that which promised to be a malignant and fatal disease deprived of its malignancy or virulence, without being astonished at the change in the type of diphtheria following the insertion of antitoxin. But there is a large, intelligent, and influential body of physicians who believe that the good results of the antitoxin treatment is due to the change of type in diphtheria. The doctrine of "change of type" of contagious and infectious diseases had its origin in the ancient belief that these affections depended largely upon what was termed "the constitution of the year." The significance of the term has entirely changed since the discovery of the microbic origin of these diseases. It is apparent that the type of a contagious affection must depend largely upon the conditions existing at the time, within and around the persons affected, influencing the life-history of the specific microbe. The whole subject of "change of type" of contagious diseases should be reinvestigated from the standpoint of modern bacteriology.

MEDICAL PROGRESS.

Version or High Forceps.—As the result of a considerable clinical experience, SCHULTZ (*Zeitschrift für Geburtsülfe und Gynäkologie*, B. xxxiv, H. 2, p. 174) formulates the following rules of guidance in the choice of either version or high application of the forceps in cases of difficult labor. Instead of prophylactic version expectancy should be observed. If the amnion has not ruptured, or immediately after escape of the amniotic fluid, version should be practised when an indication exists to terminate the labor at once. If the amniotic fluid has already been lost for some time, high application of the forceps is to be preferred to podalic version. If, under these circumstances, the os uteri is not sufficiently dilated and immediate termination of the labor is indicated, dilatation should be facilitated by multiple incisions or by means of Barnes' rubber bags. The high application of the forceps may be successfully practised in moderately contracted pelves if the os uteri is sufficiently dilated. If the degree of pelvic narrowing is considerable, the high application should be only tentative. In its failure, perforation of the head would be indicated. The high application of the forceps does not demand the same skill as version in order to bring about a successful result for mother and child. It does, however, require dexterity, although not more than any other obstetric operation.

THERAPEUTIC NOTES.

The Effects of Certain Laxatives in the Presence or Absence of Bile.—STADELMANN (*Archiv. für Exper. Pathologie u. Pharm.*, Bd. 37, p. 352,) established permanent biliary fistulæ in dogs, but allowed the animals during the night to lick up the bile which flowed from the fistulæ. Strictly speaking, therefore, they were not absolutely void of bile in their intestines, but the quantity must have been extremely small. Under these circumstances he found that the following drugs lost almost completely their laxative action: podophyllin, jalap, scammony, rhubarb, and convolvulin. Aloes and senna, however, preserved their usual action.

Buccal Leucoplasia and its Relation to Syphilis.—According to LEGRAND (*Gaz. Hebdom. de Med. et de Chir.*, December 20, 1896,) the leucoplasia which develops in old syphilitics is to be looked upon as a parasyphilitic affection in the same sense as tabes, or general paralysis. This point is important in connection with its treatment, as antisyphilitic remedies in these cases are not only without effect but are annoying and dangerous. The only safe treatment is an early surgical one, for the physician ought never to forget that these leucoplastic areas frequently degenerate into cancer.

Subcutaneous Injections of Guaiacol with Chloroform.—COLLEVILLE (*Centralbl. für innere Medicin*, No. 51, 1896,) has obtained good results in various painful lesions by the injection of from fifteen to sixty drops of a mixture of guaiacol and chloroform, in a proportion by weight of four parts of guaiacol to five of chloroform. The injections have only a local anesthetic action, but as they can be frequently repeated without disadvantage, they can be used instead of morphin not only in neuralgia and neuritis, but also to relieve the pain in rheumatism, fractures, etc.

A Case of Cancer Treated by the Roentgen Ray.—VOIGT (*Lyon Médical*, No. 51, 1896,) had charge of a man aged eighty-three who suffered great pain from a cancer situated on the left side of the tongue. There was almost constant ptyalism, with difficulty in swallowing and in opening the mouth, and there was neuralgic pain in the ear and in the occipital and facial branches of the facial nerve. For some weeks he had received daily two or three injections of morphin of a third to a half of a grain each. Treatment was then begun with the Röntgen ray, the exposures lasting from fifteen to thirty minutes each. The pain was greatly diminished from this time on. For fifteen days he either received no morphin or else a single dose in the evening to produce sleep. This treatment was continued for two months when the patient contracted pneumonia and died. During this time there was very little pain, and its absence could not be attributed to a destruction of the sensory nerves as sensation was not impaired. Nor can one think of a "suggestion" lasting eight weeks. The cancer continued to grow steadily, ptyalism persisted, and difficulty in swallowing increased. After the eighth exposure there was a marked pigmentation of the skin of the neck which afterward became almost as black as that of a negro.

Treatment of Post-partum Hemorrhage.—In an article on post-partum hemorrhage LAIRD (*Lancet*, December 19, 1896,) recommends the following method in obstinate cases: Pass the disinfected hand into the womb, close it, and with the left hand compress the uterine and ovarian arteries against it on each side. If this pressure for a few minutes does not control the bleeding, a swab of absorbent cotton saturated with a styptic and held in the palm of the hand may be squeezed from time to time, and by a slight rotation of the hand the styptic may be smeared over the whole surface of the uterus.

A New Test for Albumin and Peptone in the Urine.—YAVOROVSKY (*La Méd. Mod.*, No. 58, 1896,) adds an excess of sodium carbonate to the urine, filters it, evaporates it to one-third of its volume, then filters it again. To 4 cm. of the filtrate is added one drop of a solution of one part of ammonium-molybdid and four parts of citric acid in forty parts of water. If albumin or peptone is present, cloudiness results either immediately or after a certain time. If this is due to peptone it dissolves on warming and reappears on cooling.

Iodin Injections in Hydrocephalus.—RANKE (*Jahrb. für Kinderheilk.* Bd. 39, S. 359,) describes a case of hydrocephalus treated by iodin injections. The patient was a child ten months old. The left ventricle was punctured and 320 c.c. of serum was let out. After this 10 grams of tincture of iodin diluted with 20 grams of water was injected into the left lateral ventricle. There was a slight febrile reaction. Within two and a half weeks after the operation a noticeable diminution in the size of the head was observed. About four weeks after the treatment the patient succumbed to a fatal enteritis.

The autopsy revealed an adhesive inflammation of the walls of the ventricle into which the injection was made, with a resulting diminution in the size of its cavity.

The Best Aristol Ointment.—FAGEARDIE (*Jour. de Médicine*, December 20, 1896,) who has experimented in order to determine the best vehicle for an aristol ointment, finds that if glycerol of starch is used the aristol undergoes partial decomposition with the formation of free iodin. With vaselin there was no decomposition but the ointment was not very homogeneous. With benzoinated lard there was also a feeble liberation of iodin. With wax and with lanolin no iodin was set free, and the ointment was perfectly homogeneous. These substances are therefore best fitted to be used as vehicles for aristol ointment.

An Instance of Trional Poisoning.—GIERLICH (*Centralbl. für innere Médicin*, No. 51, 1896,) had a patient afflicted with morphinomania of a slight degree who, during a period of two months, took daily on account of sleeplessness about 45 grains of trional. Serious nervous symptoms developed. Marked ataxia, a light tremor over the whole body, and a deep depression of mind which could only be broken by strong stimulus were the chief symptoms. The memory was much affected as were writing and speech. There were no delusions. After the trional was withheld (the morphin being continued in the usual dose) the condition gradually improved, but it was five weeks before the last traces of nervous disturbance disappeared. The practical lesson in this case is that if trional is to be given for a long time, the dose must be greatly reduced or omitted altogether occasionally in order to allow its complete elimination.

Mechanical Massage of the Abdomen.—OETKER (*Deutsche Med. Wochenschrift*, No. 20, 1896,) recommends as a treatment for chronic constipation mechanical massage by means of a five-pound iron ball, thickly covered with woollen stuff and fixed in a small frame. The patient lies in a horizontal position, and rolls the ball over the abdomen. By experiments upon himself, the author determined that five minutes of this massage was sufficient to produce defecation in less than half an hour, at times of day when it was not his custom to have an evacuation of the bowels.

THE HEALTH BOARD AND COMPULSORY REPORTS.

ONE would infer from certain caustic comments recently promulgated that the New York Board of Health was planning a deadly attack upon the medical profession, instead of tendering its most efficient and kindly offices to assist in a grand campaign against the common enemy, tuberculosis. We are combatting a disease that is universally recognized as the greatest scourge of mankind. We shudder at the number of victims of the plague in India, and are ready to adopt the most stringent measures to hold it in restraint. And yet all the victims of this plague up to the present time in the entire presidency of Bombay number but few more than the individuals that fall a prey to tuberculosis in the City of New York alone every year.

The discovery of the tubercle bacillus marked a great epoch in the knowledge of tuberculosis. It was a still greater advance when science pronounced the disease infectious and communicable. But the crowning glory of medicine in this direction was achieved when we were able to say that it is a preventable and curable malady.

The medical profession of New York does not need to be told of the great fatality of tuberculosis, nor does it need further enlightenment to bring conviction of the fact that it is a communicable and a preventable disease. It will therefore be a great surprise if the profession hesitates to lend the power of its influence and its cordial coöperation in every effort to stay its course. The movement recently inaugurated by the Health Board of New York is the beginning of a grand crusade that has no less an aim than the final extirpation of the entire race of tubercle bacilli and the emancipation of mankind from his fatal grasp. This campaign is one of education simply. And it is only necessary for anyone to read the history of the work of the New York Board of Health in its supervision of tuberculosis during the past few years, as set forth in the now famous announcement of January 20th, to see how wisely the object-lessons have been presented to the people in its gradually maturing plan of education. By means of their superior and unusual laboratory and bacteriological opportunities, the medical directors of the Health Board have naturally become the leaders in this movement, and through a system of gradual extension of wise supervision and management of the victims of the disease, have evolved a complete and practical system of control. The success of it depends upon the careful execution of every component part. A weak link in a chain nullifies its entire efficiency. A single slip in one detail of the asepsis of a surgical operation thwarts the whole system. The one important link in this system which the medical profession is asked to supply is to report all cases of tuberculosis that come under its observation. The cases in the early stages, and when found among the class of people who have the intelligence and ability to properly care for themselves, are reported for statistical purposes; the more serious cases, and those found in the less prosperous classes, for inspection and control, if necessary. As the *Medico-Surgical Bulletin* says:

> No one need fear the presence of a scrupulously clean consumptive. It is the dirty sputa of dirty consumptives, and not the bodily presence, that contaminate and endanger. If the patient refuses to heroically act for his fellows (in exercising proper sanitary precautions) he can be shown the necessity of acting to save himself. If he is too stupid to grasp the facts in this direction then let the Board of Health sit in judgment on his case and condemn him to a hospital where he can be watched and compelled to be clean. Isolation is wholly unnecessary if the

patient is scrupulously cleanly. Isolation should be absolutely certain for every patient that refuses [or is unable] to be such.

What more reasonable! What more just!

The Committee on Hygiene of the New York County Medical Society, at the February meeting, presented a report endorsing and commending the action of the Health Board. That wise councils will prevail and this action of the committee be endorsed by the Society at the March meeting when the report comes up for discussion, is the expectation of all who have faith in the wisdom of the majority. The County Medical Association will discuss a motion at at its next meeting condemning the action of the Health Board. This resolution, however, has not been presented by any committee of the Society, and presumably carries only the opinion of the individual who introduced it. In the judgment of so important a measure bearing upon public safety and health there is no place for personal prejudices or exaggerated notions about individual rights and violated prerogatives. The medical profession of New York has shown itself capable on occasion of subordinating to the welfare of the community ill-considered thoughts of personal injustice and of following the illuminated path of scientific truth. These Societies will honor themselves by casting their potent influence on the progressive side of this beneficent movement.

The *Indiana Medical Journal*, in commenting upon this subject, says: "To discourage in any way this effort—even this dream, if so it prove—of relieving mankind is more than editorial atrophy; it is moral obliquity and impiety."

THE EARLY DIAGNOSIS OF TUBERCULOSIS.

WHETHER the diagnosis of tuberculosis in its early stages is simple or not, depends upon what is understood by "its early stages." It is, therefore, rather questionable teaching to maintain that the signs observed even in the earlier stages are easily enough recognized by the merest tyro in auscultation. That localized dulness at the apex, the prolonged, high-pitched expiratory murmur, the circumscribed râles, the hemoptysis, and the dry, hacking cough, are too significant to leave any doubt in the minds of the most casual observer, is true enough. But who in these days would think of regarding such physical signs and symptoms as indicative of an early stage in tuberculosis!

It is indeed commendable in our "merest tyro" to make a diagnosis even at this juncture, and he is to be encouraged in his desire to make such diagnosis, but he must not, by this flattering success, be deluded into the belief that he is recognizing phthisis in its early stage, or hope thereby to stay the progress of the disease. Our "tyro" must be informed that more modern methods of investigation have discovered instruments of such precision and tests of such reliability and accuracy that they discount by many weeks and months the date at which the stethoscope is of diagnostic value. The persistent presence of tubercle bacilli in the sputum of a patient, even when all other diagnostic signs are absent, is a menace to his welfare, and must be reckoned with by the attending physician. On the other hand, localized dulness in the lungs, with prolonged, high-pitched expiratory murmur, and circumscribed râles, with cough, fever, and emaciation, have been confidently conducted to a successful issue, when repeated examination has shown an absence of the bacilli from the sputum.

But a still more delicate criterion, and one that is rapidly coming into use among experts, is the tuberculin test. Koch has used this with most reliable and satisfactory results in five thousand cases in which physical signs were absent, and in which bacilli could not be discovered in the sputum. The Health Board has also been using it in suspicious cases, in which all other tests proved negative, with most gratifying results as to the accuracy of its revelations. And Dr. Trudeau of Saranac, in a recent personal interview declared that after careful and long continued observation he had come to regard the presence or absence of reaction after tuberculin injections as the final and decisive test in cases of supposed cure. In the case of patients who no longer present any clinical evidence of the disease, it is getting to be his custom before declaring them cured and consenting to their return to former homes and occupation, to subject them to the tuberculin test. When no reaction occurs the patient is pronounced cured, but when the characteristic phenomena are present the clean bill of health is refused. In a paper presented recently before the New York Academy of Medicine, the same authority said: "If there is expectoration and the presence of the bacillus cannot be detected by repeated and thorough examinations, a positive conclusion can often be reached within three weeks by inoculation of the expectoration in the guinea-pig, and when there is no expectoration, by the tuberculin test.''

THE VASO-MOTOR INFLUENCE OF CHLOROFORM AND ITS RELATION TO CHLOROFORM ACCIDENTS.

The fact that chloroform is a much-used and valuable anesthetic, and that it possesses dangerous properties which have prevented a great many eminent physicians from employing it, renders any information we can gather concerning its effects of superlative interest, first, because conflicting views of pharmacologists and clinicians still are met with in the journals, and, second, because a true explanation of the primary effects of the drug, and the consequent understanding of the course to pursue in order to avoid accidents, will go far toward overcoming its dangers.

The first fact to be borne in mind is that the students of the effects of chloroform have been divided into two schools, the one asserting that the danger to be apprehended from the use of the drug lies in its effect on the respiration; the other, that it paralyzes the heart and causes death by this means. It was to decide this mooted point that the various Hyderabad commissions were appointed, and that a very large number of other investigations have been carried out, among which may be named, as having been published in America, those of H. C. Wood, and the author, and others under the direction of the Hyderabad Government by the author and his assistant, Dr. Thornton, Demonstrator of Therapeutics in the Jefferson Medical College. There have been other studies of the subject made in England, notably by Gashell and Shire and by MacWilliams. These more recent studies, combined with the older ones, prove one point, viz., that chloroform is a depressant poison to all living protoplasm when brought in direct contact with it, and whether the protoplasm be nervous, muscular, or corpuscular the same lethal influence is produced if the drug be present in a concentrated form. We may start out with the fundamental fact, therefore, that the dominant action of chloroform is depressing, and that, if it comes in contact with the heart even in medicinal quantities, it tends to weaken that organ. On the other hand, if it comes in contact with the respiratory center, this protoplasm is depressed to a degree dependent upon the actual quantity of chloroform used and the individual resistance of the vital parts to its influence.

It is thus easy to understand that on one animal or human being, either in health or disease, the drug may exert a very positive effect on both the respiratory function as well as on the heart, or may expend its chief influence on one of these alone. Thus a very slight degenerative process in the heart muscle or its nervous centers, or even its dilatation and engorgement caused by violent struggling, might render these parts unduly susceptible; or the respiratory center, from some similar cause, may feel the chief brunt of the drug. I believe that it is possible for death to result from chloroform inhalation by either heart or respiratory failure, but I also believe that cases of the former are very rare, and of the latter much more common. In the first named class of cases disease of the heart is present, and there is every reason to believe that many of the chloroform deaths from heart failure, so-called, would have occurred if the patient had had to submit to an operation in which an anesthetic was not used. Indeed, there are cases on record, prior to the use of anesthetics, in which death took place from the fright and pain attendant upon the simplest surgical procedures.

The mere fact that a pulseless radial artery is found during a chloroform accident is not proof positive of heart failure, and it is interesting to note that in the cases of accident through the use of the drug collected by Thornton and myself from private sources, nearly all were reported as being due to respiratory and not cardiac causes.

In admitting that chloroform exercises a depressant effect on the heart and respiration, particularly the latter, I wish to emphasize one fact, about which there is little or no conflict of opinion in laboratory or practical test, namely, that the dominant or overshadowing influence of chloroform is upon the vaso-motor centers; and I cannot lay too much stress upon the fact that an intact vaso-motor system is as essential to life as an intact heart. The action of the heart is so closely associated with the state of the blood-vessels as to be altered the moment the arterial pressure rises or falls, for the heart, after all, is nothing more than a highly specialized part of the vascular apparatus. The capillary area of the body is so many times greater than that of the arteries that, if the arterioles relax and allow the blood to flow freely into the vast capillary networks of the muscles and glands, no blood will find its way to the veins or to the heart. Even if the heart is intact, it cannot pump blood if none is returned to it by the veins, and the familiar condition of unconsciousness, or syncope, known as "fainting," takes place. This is exactly what occurs when a patient has a sudden "bad turn" under chloroform. The agent has caused sudden dilatation of the peripheral blood paths by depressing the vaso-motor center, and the patient faints. If so much chloroform has been used that the center cannot recover itself, death occurs, for the man is bled to death in his own vessels. This condition explains the loss of the radial pulse, the failure of respiration, and the sudden peril of the patient.

Now as to the evidence to prove that the dominant action of chloroform is to depress the vaso-motor center: the experiments of all, or nearly all, investigators have shown that this drug, as ordinarily given, produces a fall of pressure, although in the first moments of inhalation there may be a rise which is due to excitement. Bowditch, Minot, Couts, Wood, the Hyderabad commissioners, my own studies, with and without Thornton, and all teachings I have ever seen, prove this fact. This is the experimental evidence; the practical evidence lies in the fact that accidents from chloroform anesthesia result more frequently when the drug is given to a patient who is in the erect or semi-erect position than when lying prone. Inversion of the body of the patient under these circumstances, even in apparently hopeless cases, will often serve to resuscitate him by causing a portion of the blood to enter the feebly beating heart from the veins, and so reach the vital centers in the medulla, as well as filling the coronary arteries, an equally important matter. Again, accidents from the use of chloroform are exceedingly rare in parturient women, because the compression of the abdominal vessels cuts off a large vascular network and the pains stimulate the vaso-motor center. Then we know that if atropin, a valuable vaso-motor stimulant, is given before the administration of chloroform, the later drug may be given with greater safety. Finally, I wish to mention an important clinical observation. On one occasion I gave chloroform to a feeble woman whose condition demanded an abdominal section. The face suddenly became pallid, the radial pulse disappeared, and the heart sounds could not be heard. The operator immediately grasped the abdominal aorta to determine if the heart had ceased to beat, and as he compressed it the pulse in the radial artery at once returned. The compression of the artery prevented what little blood the heart had to pump from flowing onward and stagnating, and, by restoring to a certain degree the normal pressure, produced a tonic cardiac influence; for the normal heart must have arterial resistance in order to perform its proper functions.

My conclusions, therefore, are that chloroform generally kills by its vaso-motor poisoning effect, which deprives the heart and respiratory center of blood, and simultaneously the drug itself aids in the embarrassment of these parts. From these conclusions we may draw the following practical deductions:

1. In all cases when chloroform is to be given to a feeble patient the extremities should be tightly bandaged.

2. Atropin should be given as a vaso-motor stimulant.

3. A large compress should be tightly bound over the abdomen if this is at all relaxed, or if an accident occurs.

4. The patient should be inverted, if syncope occurs.

5. Artificial respiration, performed by compressing the floating ribs and precordium, should be employed to aid in the circulation of the blood, to pump the chloroform vapor out of the lungs, and to aid the respiratory center in its functions.

6. During the use of chloroform the respirations should be watched for two reasons, (*a*) because the depth and rapidity of the breathing is a gauge of the amount of chloroform inhaled (for the amount on the inhaler is not the dose), and, (*b*) because as the blood pressure falls, the respiratory center becomes disturbed in its function and the irregular breathing shows that the chloroform is disturbing it. Further, irregular breathing means irregular dosing, for twenty deep inspirations a minute means more chloroform inhaled than twenty shallow ones. The respiration is the dose gauge.

7. It is useless to resort to saline transfusion in chloroform syncope, for the vessels of the body can hold many times the amount of blood in them, and unless quarts are transfused, the relaxed vascular system simply absorbs the fluid and cannot be filled.

Finally, let me mention a statement of Leonard Hill, in his excellent brochure on "The Physiology and Pathology of the Cerebral Circulation," recently published, in which he shows that chloroform so lowers blood pressure that, though the heart is still beating and draining a trickle of blood into its coronary arteries, it does not supply the respiratory center, if the blood paths are relaxed by chloroform, but that abdominal pressure restores the flow.

I could cite numerous examples in proof of the sudden and serious effects of suddenly relaxing the blood paths, but the facts I have adduced seem sufficiently convincing, and the old discussion as to whether chloroform kills by cardiac or respiratory failure, seems fair to be decided, to the effect that the influence on those functions is indirect, and that the vaso-motor effect is the important factor.[1] When chloroform is taken, blood pressure falls, the respiration is disturbed, the dose of chloroform is excessive, and the drug aids the anemia of the vital centers by a direct depressing influence.

H. A. HARE, M.D.

ECHOES AND NEWS.

An Epidemic of Scarlatina.—The alarming spread of scarlet fever at the State Normal School at Bridgewater, Mass., has caused the closing of that institution.

Western Ophthalmological, Otological, Laryngological, and Rhinological Association.—The second annual meeting of this Association will be held at St. Louis, April 8 and 9, 1897, and promises to be of much interest.

Expectorating in Cars.—It is reported from Chicago that a well-known lawyer, of prominent social and political position, has been arrested for expectorating in a street car. He threatens to sue the company for $50,000 damages.

Insanity in Egypt.—So far as could be ascertained the causes of insanity in the 477 cases treated in the government asylum of Cairo, Egypt, last year, were: Hasheesh, 88; alcohol, 9; syphilis, 27; pellagra, 11; epilepsy, 17; sunstroke, 2; grief, 30; religious excess, 16.

Bellevue Chapel Dedicated.—The Arthur Leary Memorial Chapel of the Blessed Sacrament, on the grounds of Bellevue Hospital, was dedicated February 28th. Archbishop Corrigan officiated. The sermon was a tribute to the memory of Arthur Leary and to the generosity of Miss Anna Leary, his sister, who erected the chapel.

To Investigate the Plague.—The Academy of Sciences of Vienna has sent to Bombay a commission composed of Dr. Hermann Müller, Dr. Ghon, Dr. Albrecht, and Dr. Pöch, to investigate the nature of the plague. The expenses are defrayed by the Treitle fund left to the Academy by the late Herr Treitle, and amounting to $500,000.

A Lectureship in Bacteriology.—The Linnean Society of New South Wales to which reverted the sum of $60,000 for the establishment of a lectureship in bacteriology, is now prepared to equip a laboratory, and desires to receive applications for the lectureship. The salary is $1750 per annum.

Electricity Without Heat.—By the use of chemicals in a small battery constructed by himself, Willard E. Case of Auburn, N. Y., has oxidized coal without the aid of heat and produced sufficient electricity to set a bell ringing. In a recent demonstration before the New York Electrical Society, he also made use of human blood in the same way, drawing the oxygen from the air, and produced an electric current.

Consumption in Cleveland, Ohio.—The Health Department of Cleveland announces that tuberculosis was the principal cause of death in that city in 1896. There were 265 cases. Cholera infantum came next with 255 fatalities, diphtheria 177, and typhoid fever 143. The frequency of death due to consumption seems to point out the necessity for proper isolation and other regulations. Work is now being done along these lines.

School Inspection Plan Delayed.—The N. Y. Health Department had anticipated putting into operation its plan for the daily medical examination of school children February 1st. This has been delayed, however, because the Civil Service Board has not yet finished an eligible list of the 218 physicians who were examined for appointment to the corps of medical school inspectors. Until it is furnished the board can make no appointments.

New York's Clean Streets.—The healthfulness of New York has been greatly enhanced by the clean condition of the streets. It is expensive but it pays. In a recent communication on the subject Colonel Waring says: "We have considerably less than 400 miles of paved streets on this island, and it costs us pretty nearly $3,000,000 a year to keep them in order. We sweep sixteen miles from three to five times per day; over 200 miles twice a day, and the remainder once a day."

Obituary.—Henry A. Creamer, M.D., of Brooklyn, died February 20th of pneumonia, after an attack lasting about a week. He was a native of Brooklyn, a son of the late Dr. Joseph Creamer, ex-police surgeon, and brother of Dr. Joseph M. Creamer, ex-coroner of Kings County.

---

[1] For facts showing that the apparently arrested heart is really beating in many supposed instances of cardiac cases, see my report to the Indian Government (*Therapeutic Gazette*, October, 1893), and my recent papers in the *Therapeutic Gazette*, February, 1897.

He was graduated from Bellevue Hospital Medical College in the class of 1892. He was a member of the Physicians' Mutual Aid and New York State Medical Associations.

New Training School for Nurses in Brooklyn.—The Commissioners of Charities and Corrections of Kings County propose to establish at the County Hospital a school for nurses. The need of this school has been felt for a long time but has been of necessity deferred because of the lack of room. The Commissioners are expecting an increased appropriation which will enable them to provide the additional accomodations, as well as certain wards for convalescents.

Civil Service Appointments.—The following appointments were announced February 15th from the State civil service eligible list at Albany, N. Y.: Dr. Henry Harlow Brooks, as Associate in Bacteriology at the State Pathological Institute in New York City; salary, $500. Dr. Arnold Graf, as Associate in Biology at the same institute; salary, $900. Dr. Henry P. Frost of the Willard State Hospital, as First Assistant Physician in the Buffalo State Hospital.

A Popular Hospital Fund in London.—The Prince of Wales has issued to the English Press a communication in which he suggests the creation of a fund to be called the Prince of Wales' Hospital Fund for London, to commemorate the sixtieth anniversary of the Queen's accession to the throne. The object is to secure about £150,000 annually by subscriptions of a shilling and upward to meet the needs of the hospitals which are not met by existing funds.

Inspection of School Children in New York.—*Pediatrics*, in commenting on the recent regulation of the Board of Health regarding the inspection of the public schools, says: "A school inspector might be tempted to add to his salary of $300 a year by taking charge of such cases as he may detect in his rounds of inspection, thereby robbing the regular family physician of a patient;" and suggests that the Board of Health pass such rules as will safeguard the general practitioner and remove from the inspectors the temptation to use their opportunities to their own advantage.

The Passaic Valley Sewerage.—The report of the Passaic Valley Sewerage Commission has been submitted to the New Jersey State Legislature. The conclusions of the commission are that the Lower Passaic River is so polluted as to constitute a public nuisance, requiring immediate remedy, and that an act of the Legislature should be passed authorizing the construction of a trunk sewer and branches to conduct the sewage of the cities and towns along the lower river to the tide water of Newark Bay.

The Wisconsin Diploma Mill.—It is reported from Chicago that Frederick Rutland, who calls himself a doctor, and President of the Wisconsin Eclectic Medical College, has been arrested by the government officers on the charge of using the mails to defraud. It is claimed he has been issuing fraudulent medical diplomas upon the payment of sums ranging from $10 to $50. His method has been to allow the student to "study at home," and then to forward a diploma upon receipt of the money and the answers to a set of questions. He claims to have graduated 907 students last year.

Diphtheria Antitoxin Still in Demand.—In the recent discussion on diphtheria before the N. Y. Academy of Medicine, Dr. Winters remarked that it was a significant fact that while the New York Board of Health one year ago kept eight horses for the production of antitoxin they now had only four. In reply to this, Dr. Park of the Board of Health, said that at the present time the serum sent out by the Board was five times as strong, bulk for bulk, as formerly, and this explained the fact that fewer horses were therefore needed. As a matter of fact, however, nine horses instead of four were now used for this purpose.

Report of Committee on Hygiene of the New York County Society.—Realizing the need of proper measures to prevent the spread of pulmonary tuberculosis, and regarding it as an essential preliminary that all physicians be impressed with the importance of making an early diagnosis of the same by microscopical examination of the sputum, we earnestly recommend that physicians avail themselves of the offer of the Bacteriological Department of the Board of Health to make such examinations. We approve of the compulsory reporting of cases of pulmonary tuberculosis, if the inspectors are forbidden to visit or to have any communication with the patients without the consent of the attending physician, believing that the attending physician is capable of giving all the necessary instructions. W. H. Katzenbach, Chairman; J. Harvie Dew, Robert C. Myles, Chas. N. Dowd, Egbert Le Fevre.

Western Surgical and Gynecological Association.—The sixth annual meeting of this flourishing association was held in the Senate Chamber of the State House at Topeka, Kan., December 28 and 29, 1896, and was largely attended. Many interesting papers were read and discussed. Denver was chosen as the next meeting place. For the ensuing year the following officers were chosen: President, Dr. Joseph Eastman of Indianapolis, Ind.; first vice-president, Dr. D. S. Fairchild of Clinton, Ia.; second vice-president, Dr. B. B. Davis of Omaha, Neb.; secretary and treasurer, Dr. Herman E. Pearse of Kansas City, Mo. Executive board—Dr. L. Schooler of Des Moines, Ia.; Dr. M. B. Ward, of Topeka, Kan.; Dr. T. J. Beattie of Kansas City, Mo.; Dr. C. Lester Hall of Kansas City, Mo., and Dr. J. P. Lord of Omaha, Neb. Dr. W. W. Grant of Denver was chosen chairman of committee on arrangements.

The Health of Chicago.—During the month of January the total number of deaths from all causes in Chicago was 2026, or 1.25 per 1000, the population reckoned at 1,619,226. Of this number, consumption claimed 187 victims, pneumonia 290, bronchitis 172, diphtheria and membranous croup 76, cancer 67, typhoid fever 38, other acute intestinal diseases than typhoid 139, heart disease 105, and nervous disease 186. Two hundred and seventy-three cases of diphtheria and 87 of scarlet fever were reported, and 11,733 persons were vaccinated. Of the reported cases of diphtheria, 125 were bacterially verified as true cases of the disease, and 120 of the patients received treatment with antitoxin, 112 of whom recovered. Ninety-eight persons received immunizing doses of antitoxin, and none of these developed the disease. It is interesting to note that the age of those attacked ranged from a few weeks to over ten years, and that of those who recovered 17 received the injection on the first day of the disease, 29 on the second day, 29 on the third day, 21 on the fourth day, and 28 on days later than the fourth. Of the fatal cases, 1 patient was injected on the second day, 3 on the third, 1 on the fourth, and 3 later than the fourth day. All of the cases resulting fatally had severe complications, the gravest being one of nasal diphtheria with septic pachymeningitis. Four were intubation cases. Forty per cent. of all cases showed a mixed streptococcus and staphylococcus infection.

Regulation of Hospital and Dispensary Work in the District of Columbia.—The Medical Association of the District of Columbia has adopted the following resolutions: (1) That every institution for medical charity shall require from every applicant for relief in a hospital or dispensary, a written certificate to be obtained as hereinafter provided. Emergency cases are to be exempted from this rule. (2) That such certificate be obtained from Physicians to the Poor, the Board of Associated Charities, and any registered physician. (3) That cases of sick and injured persons found upon the streets, in the stations, or elsewhere, who require immediate treatment, shall be carried to the Emergency Hospital, or to the nearest hospital having an emergency service, or to their homes, if so directed by the patient or his friends. (4) That emergency patients shall not be detained longer in such institutions than the necessity of the case imperatively demands, but shall be discharged from the service and sent to their homes or to some public hospital as the patient may elect. (5) That members of this Association shall be entitled to the privilege of attending private patients occupying private rooms in any of the public hospitals of this city. (6) That in future the members of the medical staff of hospitals when attending medical or surgical cases in private pay-rooms shall insist upon proper payment for their services, except in the case of such patients who are clearly unable to pay for same. (7) That whenever the medical staff, or a majority thereof, of a hospital or dispensary resigns, and, when after due hearing, this Association finds that the resignations were for just and sufficient cause, it shall be forbidden for any member of this Association to accept a position on the staff of said hospital or dispensary. (8) That whenever one or more members of the medical staff of a hospital or dispensary are dismissed, and when after due investigation, this Association finds that such dismissal was without just and sufficient cause, it shall be forbidden for any member of this Association to fill the vacancy created thereby. (9) That complaints made under Rules 7 and 8 shall be made in writing to the Standing Committee, which after due consideration shall report its findings to the Association.

Serum Diagnosis of Typhoid Fever.—Dr. Gehrmann and his assistant, Dr. Wynkoop, of the Chicago Board of Health, furnish the following note concerning their work with the Widal-Johnston application of the Pfeiffer test for typhoid fever: "The systematic examination of suspected typhoid cases for physicians was begun by the laboratory November 20, 1896. Up to January 31, 1897, 158 cases had been subjected to the test. In 99 cases the typhoid reaction was observed, and in 59 it was absent. In 57 cases, subsequently proved to be typhoid from the clinical course, the reaction failed in 5 and a negative report was rendered. We attribute this to the hurried examination often required, and failure upon the part of the physician to send enough blood. Pseudoreactions have been numerous. Eight cases of pneumonia and one case of bronchitis and pleurisy, giving typical pseudoreactions, were of special interest, in that this is the greatest number of cases of any one disease other than typhoid examined by us. The reaction was entirely absent in only one instance—where the clinical diagnosis was pneumonia. Owing to the increased occurrence of pseudoreactions where the dried blood, with all its albuminous elements, is used, we have decided regularly to delay reporting the result until from eighteen to twenty-four hours after beginning the examination. This may cause some inconvenience to physicians, but by waiting the reaction can be so far verified as to make it really pathognomonic. The additional evidence toward the diagnosis is obtained by observing the increasing development of the reaction when the preparation is maintained at blood heat, or by the entire disappearance of the pseudoreaction and a very marked increase in the numbers of bacilli present. We have found that it is not specially necessary to use attenuated or old typhoid cultures to obtain good results when the observation is prolonged for such a period. The reverse of the typhoid-serum diagnosis in the differentiation of cultures from water is now used in such cases as show growth for the typhoid-coli group of organisms by the method of Parietti. So far no culture has been isolated from the water supply of the city that would give the reaction with serum from typhoid cases, although we have recently found *B. coli communis* in a number of instances. It has been impossible on this account to make use of the method for rapid diagnosis of typhoid in water as was at first hoped. Apparently it can be of value only in the differentiation of cultures after the usual methods of separation of suspicious organisms."

OUR PARIS LETTER.

[From our Special Correspondent.]

DIPHTHERIA GERMS IN THE NORMAL THROAT—DIFFERENTIATION OF PATHOGENIC BACTERIA—BEHRING'S MODEST VISIT TO PARIS—NOCARD WINS THE LACAZE PRIZE.

PARIS, February 4, 1897.

AFTER having labored long and conscientiously to make it clear that certain particular forms of bacilli were always the necessary cause of certain specific diseases, it would seem now as though bacteriology was about to confess that pathogenity is not essential to anẏ form of bacillus; that one may have present certain special forms of bacilli, that up to this have been considered specifically pathogenic for certain diseases, without the production of those diseases; in other words, that the pathogeneity of a bacillus, or family of bacilli, is dependent upon some modifications of the bacillus due to climatic or nutrient conditions, or due to its passage through individuals under certain circumstances, causing an increase in its virulence.

Probably the first thing that set the current of thought seriously in this direction was Roux' and Yersin's discovery of the diphtheria bacillus in a large number of normal throats, and in parts of the country where diphtheria had not been epidemic for years. This experience is not uncommon in America and has been made one of the stock arguments—probably the most effective one—against the statistics of diphtheria as treated by antitoxin, there being no doubt that numbers of cases are treated as diphtheria by the antitoxin that would not have been considered diphtheria at all a few years ago; bacterial diphtheria it may be, but without the clinical symptoms.

After this came the description of various technical methods of differentiating two very important bacilli (Eberth's typhoid bacillus and the cholera bacillus) from a host of very similar bacilli rather widely spread in nature. For a good many years this effort at differentiation was thought to be successful, though newer and constantly newer technical methods had to be invented, each more complicated than the last, in order to enable the bacteriologist to decide with certainty as to the presence of the specifically pathogenic germ for these two diseases. Water statistics collected during the years that marked the progression in technical manipulations became almost completely valueless from the standpoint of typhoid and cholera.

Now the leaders seem to be giving up the effort at further differentiation and are coming around to the view that it is a family of bacilli one has to deal with in each of these diseases. Some of the members of each family are specially pathogenic and some are not. These last may become virulent under certain conditions not well understood, but the main one seems to be the passage of the bacillus through one or more individuals whose lowered resistive vitality make them subject even to the originally attenuated virulence of the bacilli. This gain in virulence by passage through a series of animals is, of course, well known and founded on any number of observations.

Roux, in his lesson on typhoid before Christmas, in the course at the Pasteur Institute, showed how strongly his views were tending toward the belief that changes of virulence dependent on biotic changes in the protoplasm of microbes were the rule rather than the exception and that microbes specifically pathogenic at one time may not be so at another; or, what is still more important, that non-pathogenics may become, at a given moment, virulently pathogenic. In his remarks on diphtheria, the same tendency was evident. Metschnikoff, in his masterly review of the microbiology of cholera, that maze out of which there seems no sure road, and which has been for him a subject of very special study, gave as his conclusion that the comma bacillus, usually considered as the cause of cholera, was widely spread in water in many places, practically all over the world, and that its specificity in the etiology of cholera was due to extrinsic circumstances that modified its virulence. This, too, despite the claims that are made for Pfeiffer's reaction as a criterion by which to separate the true and false cholera bacillus, for in the lakes at Versailles, where there had been no cholera for years and where there had never been anything approaching an epidemic, it being one of the few places close to Paris always exempt, bacilli were found that, after having been submitted to all the tests possible at the Pasteur Institute, were pronounced indistinguishable from true cholera bacilli. They were then sent to Pfeiffer himself at Berlin, who announced that some of them reacted positively to his test and were to be looked upon as true cholera bacilli, though others did not.

Duclaux, who is Pasteur's successor as the Director of the Institute Pasteur, is giving a series of lessons on the biological chemistry of water. He, too, shares the opinion that it is a family of bacilli sometimes pathogenic, sometimes not, and widely spread in nature that we are dealing with in the microbiology of typhoid and cholera. With regard to typhoid, he is as positive as is Metschnikoff regarding cholera. He referred especially to some work unpublished when he spoke, but which has since been reported to the Society of Biology. Two physicians in the military service at Val de Grâce have found, as far as all bacteriological tests are concerned, true typhoid bacilli in the dust of the floors of wards in the hospital where there had been no typhoid cases for years. Duclaux deprecates that this seems to make doubtful the hygienic precautions with regard to water supply that seemed so simple and so sure. For it would seem that these bacilli are so widespread in nature and so liable to become pathogenic, though they may not have been before virulent, that the simple hygienic precaution of protecting the water supply from human contamination, thought all-sufficient up to this time, may prove illusory.

It has just leaked out that Behring, returning from his wedding tour, stopped off at Paris to visit the Pasteur Institute, but with the distinct understanding that he was to be absolutely incognito to the general public. He and Roux are great friends, it seems, and are rivals in more than serum-therapy, for from this incident Behring would seem to shun popular acclamation as much as does his confrère of the Pasteur. Behring would have been given a very flattering reception in Paris by many more than the medical profession had he cared to accept it. This charming modesty of the true scientist is really delightfully refreshing as a change from the selfish, childish pretension one sees so much of in the lesser lights of the profession, whose little candles, verily, will not be hidden under a bushel if they can help it.

In company with Roux, Behring visited Alfort, where, with Nocard, he saw the action of Marmorek's serum in a case of anasarca of the horse, a streptococcic disease common enough here in France. It would have been interesting to see the three men, whose names are greatest in that new world on which is rising the sun of serum-therapy, making their observations together on the sick horses at Alfort. One wonders if the antivivisectionists would not realize after a sight like that how much of good for the animals is coming, too, from the experiments made on a few of them by the scientists, and how closely their health is bound up with that of human beings in the advances that are being made. Behring pronounced himself as assured of the success of Marmorek's serum.

In an interview with Capitan published in *La Médecine Moderne*, he is reported to have said that he had complete confidence in the serum for the cure of the bubonic plague that is being made at the Pasteur Institute, and with which Yersin's successes had just been reported at the time of his visit. Behring said a little, but very little, of his own work at present. He has an antituberculous serum that, injected into guinea pigs at the same time with the bacilli of tuberculosis, prevents them from dying from the disease. He thinks that this would be successful in human beings, in cases of acute tuberculous meningitis or generalized tuberculosis; but, in general, the amount of the toxin of tuberculosis circulating in the blood of a consumptive patient at any given time is such an indefinite affair that the dosage of the antitoxin is difficult to arrange.

The Academy of Medecine has just announced that the Lacaze prize of 10,000 francs is conferred upon Prof. Nocard of Alfort for his work on tuberculosis. His labors on the diagnosis and prophylaxis of bovine tuberculosis with Koch's tuberculin are very well known. He it is who pointed out very clearly the virulence of the blood, meat, and milk of tuberculous cattle, after having shown the identity of bovine and human tuberculosis. His work with Strauss on the rôle of contagion rather than heredity in the production of tuberculosis is also well known. The comparatively recent discovery by himself and Roux that cultures of the tubercle bacillus could be readily and rapidly made in ordinary culture media to which glycerin had been added has made observation of the bacillus much easier, and has brought much nearer to us the possibility of serum-therapy for tuberculosis.

TRANSACTIONS OF FOREIGN SOCIETIES.

London.

PERFORATING TYPHOID ULCER SUCCESSFULLY SUTURED—PERFORATION OF THE GALL BLADDER OCCURRING IN TYPHOID FEVER—LIGATION OF THE SUBCLAVIAN ARTERY FOR TRAUMATIC ANEURISM—HEMOPERICARDIUM—RESECTION OF THE SIGMOID FLEXURE FOR CARCINOMA—SUCCESSFUL SUTURE OF A PERFORATING GASTRIC ULCER.

AT a meeting of the Royal Medical and Chirurgical Society, held January 26th, **BRUNTON** and **BOWLBY** reported a case of *perforating typhoid ulcer successfully treated by laparotomy and suture.* The patient, a man aged thirty-seven years, was admitted to the hospital at the end of the second week. The typhoid fever was of a severe type. It was complicated by hemorrhage and by a relapse, which occurred at about the end of the sixth week and lasted nearly a fortnight. Four weeks after the subsidence of fever there was a severe attack of abdominal pain, followed after some hours by tympanites and symptoms of obstruction, but without nausea or vomiting.

Eighteen hours after the attack of pain began the abdomen was opened in the middle line below the umbilicus. No gas or fecal matter was discovered until the adherent omentum was separated from the coils of small intestines. Then about half a pint of dirty serous fluid mixed with intestinal contents escaped. With little trouble an indurated coil of intestine was separated and drawn out of the abdomen. The perforation was about the size of a small pea, and was situated opposite the mesentery in an area of induration thought to be an inflamed Peyer's patch. The opening was closed by ten silk sutures introduced according to Lembert's method, the outer row of which passed through normal bowel. The suture line was tested and found to be water-tight, and the lumen of the bowel at this point was not unduly constricted. Thick masses of old and recent lymph were removed from the other intestinal coils, and the abdomen was irrigated with hot water until all foreign matter seemed to be quite removed. A drainage tube was passed into the pelvis and the wound sutured. The operation lasted forty minutes, and was not followed by collapse. Recovery was uneventful. The tube was removed in forty-eight hours, and for four days nothing was given by the mouth except water in teaspoonful doses. The bowels moved on the fifth day, after an enema. For several weeks after the operation the patient had a slight, dragging pain in the abdomen, but this gradually passed away. The case was one unusually well adapted to operation and can not be compared with those cases in which perforation occurs during the height of the fever in patients greatly prostrated by the disease.

HERRINGHAM and **BOWLBY** reported a case of typhoid fever in which laparotomy was performed during convalescence for the relief of symptoms supposed to be due to perforation. No lesion was found, and recovery followed. This case throws doubt upon the recorded spontaneous recoveries after supposed perforation in typhoid fever. It has been pointed out by Fitz that there are no trustworthy signs which are pathognomonic of perforation. Symptoms similar to those which occur after perforation, namely, acute pain, frequent vomiting, and small pulse, with rigidity and tenderness of the abdomen, may be due to a local peritonitis, or simply to constipation.

MOORE thought that the usual date for perforation is not as early as is often stated. It is of assistance to remember that the perforation is usually near the ilio-cecal valve. Out of twenty-one consecutive cases at St. Bartholomew's Hospital the perforation was found to be within two feet of the valve in one-half of the cases, and within three feet of the valve in three-fourths of the cases. He said he had never seen any adhesions at the *post-*

mortem which would indicate the spontaneous healing of the perforation.

Goodall thought the symptoms in some of the reported cases which recovered spontaneously might be due to a suppurating mesenteric gland.

Hawkins described a case of *perforation of the gall bladder occurring in typhoid fever.* Jaundice occurred about one week after the beginning of the disease, and was preceded by severe pain in the right hypochondriac region, as well as in the lower portion of the right axilla. This pain increased and extended to the umbilicus. There was a temperature of 105.8° F., and a dry pleurisy developed on both sides. Three weeks later the patient died with extreme cyanosis, respirations of about sixty per minute, and more or less constant hemorrhage from the bowels. At the autopsy the right pleural cavity contained ten ounces of turbid fluid. There was slight consolidation at the base of both lungs. The gall bladder was adherent to the peritoneum about a perforation in its anterior wall. It contained a free gall stone and a quantity of purulent fluid.

Harley mentioned a similar case. Adhesions prevented extravasation, but an epigastric swelling developed. This was excised, and many small calculi and some colorless bile were evacuated.

Croly showed before the Clinical Society, January 22d, a case of *ligation of the second part of the subclavian artery for aneurism* in a man aged thirty years, who was stabbed with a pair of tailor's scissors. The hemorrhage was stopped without difficulty, but a tumor formed above the clavicle, which pressed on the brachial plexus and greatly disturbed the health of the patient, causing also pain and paralysis. Two years after the injury the subclavian artery was tied with ligatures made of gold beaters' skin. The radial pulse returned in four weeks, and the paralysis rapidly improved.

Moullin showed a case of *hemopericardium.* The patient, aged twenty, was struck on the sternum during a football game. He continued playing for twenty minutes, and then returned home and suddenly collapsed. There was some difficulty in swallowing, and great pain on the left side. The temperature was 96°, F., and the pulse 60. No urine was excreted for twenty-four hours. Thirty-six hours after the accident a violent cough, with profuse expectoration, developed, with a pulse of 140, respiration of 22, and temperature of 100.4°, F. The area of cardiac dulness gradually increased. Three weeks later he was seized with dyspnea, and the whole of the left chest was found distended and motionless. The heart sounds were audible only in the second right interspace. The pericardium was incised in the fifth space, and a drainage tube inserted. Within three hours six pints of fluid blood escaped and clotted firmly in a basin. Dyspnea at once disappeared. The tube was removed on the following day, and the patient was able to sit up at the end of a week. The left lung remained collapsed for a long time, although there was finally perfect recovery.

Lucas ligated the femoral artery for elephantiasis, following thrombosis of the left internal saphenous vein, in a man aged forty-five. Primary union followed, and three weeks later the circumference of the calf was two inches less than before the operation.

At a meeting of the Medical Society, held January 25th, **Allingham** showed a patient, aged sixty-four, from whom he had *removed a portion of the sigmoid flexure containing a carcinoma.* Bobbins of decalcified bone were used to make an end-to-end approximation, There was a slight feco-purulent discharge through the wound, but this soon ceased of itself.

Turner had occasion to perform laparotomy twice upon the same woman for strangulation of the bowel. At the first operation the strangulation was found under a band in the right iliac fossa. There was a rapid and complete recovery. Six months later she was seized with sudden pain and vomiting, and the abdomen was reopened. Strangulation had taken place under a band in the right hypochondriac region. This band was due apparently to inflammation associated with the previous attack,

At a meeting of the Pathological Society, held February 2d, **Stephens** and **Parfitt** showed specimens of three cases of hemorrhagic diphtheria. In all of them purpura and hemorrhages from the mucous membranes developed, with death from septicemia. In every case cultures from the lungs contained diphtheria bacilli. Cultures from the blood in one case contained diphtheria bacilli, in another pneumococci, while in the third both diphtheria and streptococci developed.

Before the Esculapian Society January 22d, **Silcock** described a case of perforating gastric ulcer occurring in a young unmarried woman. He sutured the perforation twenty-four hours after the attack commenced, with complete success. The perforation was in the anterior wall of the stomach toward the cardiac end. The gastric contents had escaped freely, producing peritonitis. Owing to the thickened and friable condition of the stomach wall about the perforation, the stitches in its immediate vicinity would not hold, and it was necessary, therefore, to fold into the organ a considerable tuck, a procedure that has been made use of to cure dilatation of the stomach.

At a meeting of the Liverpool Medical Institution held January 28th, **Thomas** showed a girl aged fifteen upon whom he had operated for "saddle nose" by inserting a piece of celluloid under the skin. The deformity was thus completely corrected, and the celluloid had remained in position for seven months without causing any inconvenience.

Banks related a case of a girl struck in the abdomen by a "swing-boat." There was a central abdominal swelling from the xiphoid cartilage to the umbilicus, and pain, vomiting, and fever. A median incision revealed the great omentum spread over the tumor. Through it a trocar was introduced, and thin greenish fluid escaped. A drainage tube was kept in position for several weeks. The case was regarded as one of hemorrhage into the small omental sac.

Berlin.

SYPHILITIC MYOCARDITIS—CYSTS OF THE ANTRUM OF HIGHMORE—RHINOSCOPIA MEDIA.

At the session of the Union for Internal Medicine held January 18th, **Rosenthal** presented a young man who acquired syphilis in 1895. Recently he made a considerable journey on a bicycle, drinking a great deal, and exhausting himself by hard riding. He presented the symptoms of rapid irregular pulse, a systolic murmur over the mitral and pulmonary valves, an increased second sound, and an extension of the cardiac dulness toward the right. Rosenthal looked upon the case as one of *syphilitic myocarditis.* The seat of the lesion often being determined by traumatism, in this case it was the heart which had been subjected to abuse. The prognosis was favorable.

At the Laryngological Society, October 30, 1896, **ALEXANDER** spoke of the cysts which arise from the mucous lining of the antrum of Highmore. He described seven cases in which the cysts contained a serous fluid. He admitted that the presence of such fluid free in the antrum, without the formation of a cyst, is theoretically possible, but thus far it has never been demonstrated.

KIRSTEIN spoke of his experience with a method of investigating the superior portions of the nose, proposed by Killian and called "rhinoscopia media." After cocainization a narrow speculum is introduced into the nasal cleft and opened. By this means the middle turbinate is dislocated, usually with an audible fracture. The procedure in some cases is easily carried out; in others, it is quite impracticable. The method is recommended only in those cases in which it is clinically important to obtain an accurate view of the superior nasal passages, for example, in cases of polyp. Kirstein has never seen any serious results follow this rather violent method of examination.

SOCIETY PROCEEDINGS.

THE NEW YORK COUNTY MEDICAL SOCIETY.

Stated Meeting held February 22, 1897.

The Vice-President, ROBERT A. MURRAY, M.D., in the Chair.

THE DIAGNOSIS OF MALARIA.

WILLIAM OSLER, M.D., of Baltimore, read a paper with this title. (See page 289).

DISCUSSION.

DR. WALTER B. JAMES said that he thought most physicians in this section of the country would agree with Dr. Osler that malarial fevers were fairly typical, and easy of recognition, even without the aid of the microscope. He had examined the blood of many patients in this city, since the time of Laveran's discovery of the plasmodium was proved to be correct, and he had come to the conclusion, as a result of these studies, that malaria, originating in New York City, was rare. Since he had relied upon this method of confirming the diagnosis of malaria, the cases of malaria had become much fewer. They usually originated in some other locality than New York City, or beyond the thickly settled portion of the city, or on some ground floor, or in a house near some extensive excavation. He had never found the parasite of the irregular or remittent malarial fevers in an individual whose history indicated that the disease had been contracted in this locality. He had found this parasite in a fair number of cases among sea-faring persons, and others who had most probably contracted the disease in other regions. His observations indicated that we had to deal here almost exclusively with the tertian parasite, or that form of the disease which is most easily recognized.

He wished at this time to say a word in favor of the old-fashioned clinical method of diagnosticating malarial fever, for it had seemed to him that the finer methods of diagnosis had somewhat blunted our other powers of observation. In his opinion, a careful study of the clinical aspect of almost every case of malaria in this city would result in a trustworthy clinical diagnosis. The absolute recognition of the parasite in the doubtful cases must be entrusted to the "malarial *expert,*" for it must be rare to find a general practitioner whose training and experience had been sufficient to make him competent to establish the diagnosis in the *doubtful* cases—in other words, in just those cases in which the question of diagnosis assumes unusual importance.

DR. A. JACOBI said he agreed with the last speaker that in many cases the diagnosis could be made without recourse to the microscope, but the microscopical test was of much value, and it should not be forgotten that the best clinicians throughout the world had been exceedingly glad to be able to appeal to the microscope for a confirmation of the diagnosis of malaria.

As to the diagnosis, he would say that it was rare to find diseases in which there would be such a high elevation of temperature as in malaria, although, of course, at the beginning of a pneumonia or a tonsillitis such might occur. Again, he knew of no other disease in which the swelling of the spleen was so considerable as in malaria. When the spleen could be distinctly felt below the free border of the ribs within a few days, the probability was that the disease was malaria, and not typhoid fever. Ehrlich's diazo-test, it was true, was also observed in pneumonia, acute miliary tuberculosis, and other diseases, but in a great many instances he had found it serviceable for differentiating between malaria and typhoid fever in very doubtful cases. As a rule, he had not found the maroon discoloration that was observed in typhoid fever from the fourth to the fourteenth day. In cases of auto-infection, which might be conveniently termed "intestinal fever," there was an irregular fever which, in children, might last for a number of weeks. This affection was frequently mistaken for typhoid fever, and not infrequently for malarial fever. It was a common affection here, where children were habitually overfed. In this affection there was usually only very slight swelling of the spleen. Its true nature was to be determined by watching the effect of a good purge and a restriction of the diet. In some cases of acute rachitis there would be found a fever presenting some of the features of malaria; indeed, a few very excellent clinicians had been led into error in this way. At one time he had seen here a number of cases of malaria originating in South Brooklyn, before that portion of the city had been properly sewered. In these cases, the prostration was very marked and persistent, and a distinct paroxysm of ague often failed to develop for a long time. He had noticed, however, that after the first dose or two of quinin it was not very unusual for a severe paroxysm to occur. On pushing the remedy, improvement would be noted, and convalescence would soon be established. This rather remarkable phenomenon had puzzled him a good deal at the time. He had since endeavored to explain it by supposing that the administration of the quinin at first had caused a contraction of the spleen, and that the constant return to the circulation of a number the malarial organisms had resulted in the development of the ague paroxysm.

DR. E. LE FEVRE said that he had made quite an extended study of malaria at Bellevue Hospital. The microscopical examination in the large majority of cases showed single or double groups of the tertian type. Two cases of the pernicious type had been admitted to the hospital with a diagnosis of apoplexy. One of these patients was an old lady, and the correct diagnosis had only been made in her case after finding a large number of the malarial organisms in her blood. She had had a continuous temperature of 104°, F., according to the records of another hospital, for some little time previously. The organisms disappeared rapidly under the use of quinin. The other case was that of a man who lived on the fourth story of an apartment house, and apparently under perfect sanitary surroundings. As far as could be ascertained from the history, this case had developed in New York City. His experience had been that quite a number of the cases had developed in the southern part of this city. Eleven of the cases had presented types of plasmodium that he had been unable to classify. In only a small percentage of the cases had it been possible to feel the spleen below the free border of the ribs.

DR. S. BARUCH said that having been at one time a resident of the Southern States he had had extensive experience with true malaria. He regarded the diagnosis of malarial fever as more easily made than in any other disease. He depended more upon the temperature than on any other sign. It was not the height of the temperature so much as the difference between the temperature at the beginning of the paroxysm and that at its acme. Such large excursions of temperature were not observed in any other common disease. It was, however, observed sometimes in gall-stone fever and in ulcerative endocarditis. One observer had noted the occurrence of a similar fever in those addicted to morphin. In his experience, splenic enlargement had been so infrequent in the early stages as to be of little importance in making the diagnosis.

Mention had been made in the paper of the large number of recorded cases in which malaria had been alleged to be the cause of death in this city and Brooklyn. In a paper published by him in 1881 he had directed attention to this subject, and had shown that out of 130 reported cases of this kind, careful inquiry had shown that in only thirty had the physicians who had thus signed the death certificates been willing to state positively that, in their opinion, malarial fever had really caused death.

DR. OSLER, in closing the discussion, said that his statement regarding the number of reported fatal cases in this section of the country had been founded on the figures given in the United States census for the six years ending in 1890. According to such statistics, the mortality from malaria was simply appalling, but in all probability nearly all of these cases were really typhoid fever. He had taken pains to make inquiry in both New York and Brooklyn, and had learned that fatal cases of malaria were exceedingly rare in those cities. The sooner the physicians of the North learned that north of the Chesapeake death from malarial fever was exceedingly rare, the better for the accuracy of our statistics. He could not agree with those who had stated that splenic enlargement was rarely observed in the early stages of malaria. If the patient were placed on the side, and the hands used to push the spleen up toward the palpating finger, there would be little difficulty in most instances in feeling the enlarged spleen. The clinical diagnosis of ordinary malaria was exceedingly easy; it should be possible to make it in about nineteen out of twenty cases from the facies alone, after the affection had lasted for a week or ten days. The fresh, or untreated cases usually gave a very distinctive paroxysm. The height of the fever was certainly an important factor in the diagnosis. It should be recognized that the irregular type of fever might produce a definite and specific fever, and the paroxysm would be found different from the other form. In these exceptional cases, the temperature curve was very much longer. He had seen two instances in which the fever in a morphin habitué closely resembled malaria, but in these cases no malarial organisms were found.

In conclusion, he would say that malarial fever was a very rare disease north of "Mason and Dixon's line"—except in the heads of the doctors.

REVIEW.

THE ETIOLOGY, SYMPTOMS, AND TREATMENT OF GALL-STONES. By DR. J. KRAUS, SR., of Carlsbad, with additional remarks on Operative Treatment by HENRY MORRIS, M.B. (Lond.), F.R.C.S., Surgeon to the Middlesex Hospital. London: Kegan, Paul, Trench, Trübner & Co., 1896.

THIS little book, a translation by the author of his "Beitrage zur Pathologie und Therapie der Gallensteine," offers a clear and very readable account of the troubles caused by gall-stones, and their treatment. Written by a physician at Carlsbad—that Mecca of gall-stone sufferers—we are not surprised to find therein an excellent account of the disease. The author discusses the morphology of gall-stones, their etiology, symptoms, diagnosis, prognosis, and treatment. Dr. Kraus lays considerable stress on what he calls the "prodromal state of cholelithiasis," and expresses surprise at finding so little mention of it in literature. He deplores the fact that so few patients come under the physician's care during this stage. Kraus is a firm believer in the virtues of Carlsbad in the treatment of gall-stones, but declares that a course of the waters at home, if properly used and directed, would meet with the same success as at Carlsbad itself.

Mr. Henry Morris contributes a short account of "The Surgical Treatment of Gall-stones and the Complications Arising from Them." According to Morris, aspiration of the gall-bladder with trocar and canula should never be attempted. To any one who desires a clear and concise account of the subject, we recommend this little volume.

THE MEDICAL NEWS.

A WEEKLY JOURNAL OF MEDICAL SCIENCE.

VOL. LXX. NEW YORK, SATURDAY, MARCH 13, 1897. NO. 11.

ORIGINAL ARTICLES.

THE SIGNIFICANCE OF PAIN.

BY W. H. THOMSON, M.D.,
OF NEW YORK;
PROFESSOR OF THE PRACTICE OF MEDICINE IN THE NEW YORK UNIVERSITY.

SECOND PAPER.

PRESSURE PAINS, as their name implies, are due to the encroachment of tumors, abscesses, aneurisms, or other causes of direct pressure brought to bear upon nerves anywhere along their course. Their chief characteristic is that they are essentially continuous. Though these pains may be aggravated into paroxysms of greater or less severity, yet they differ altogether from the large class of neuralgic pains with which they may be confounded by the fact that they never wholly intermit. There always is some uneasiness left at the seat of the pressure, however much the pain has lessened in degree. The reason why they are mistaken for neuralgic pains is because they do not show the character of inflammatory pains in being increased by pressure or movement, or by producing muscular stiffness, except sometimes abdominal muscular rigidity in the case of gastric or pancreatic tumors. We always, indeed, have reason to suspect that a fixed or stationary pain is something more than functional, and most likely due to an organic mischief, however hidden that may be. On the other hand, pressure pains may present a seeming resemblance to inflammatory pains when the pressure mechanically interferes with the function of the parts or organs implicated. Thus in brain tumors or abscesses the small room in the cranial cavity for any displacement may cause many symptoms of functional disorder of the brain to accompany a pressure pain there. Except in the case of brain abscess, however, the absence of fever and of other accompaniments of inflammation will ordinarily suffice to indicate the true nature of the pain. In other parts of the body the disturbance of function caused by pressure is different from that caused by inflammation, in that the function is embarrassed, rather than excited, while the pains are evidently not so closely connected with the functional actions themselves as they are in inflammation.

Pressure pains are apt to radiate more widely than any other kinds of pain when the pressure involves large trunks or plexuses of nerves. They differ in such cases from radiated inflammatory pains in their greater variety of range. But however far they may travel, they are always characterized by having a central focus or headquarters where pain is never absent and to which they can be traced. A careful examination then will show that whereas pain is constant at the original focus, those which radiate from it, though they may seem much more severe, yet are quite subject to variations. Thus, years ago, a phthisical patient of mine began to have agonizing pains in his legs, which he very distinctly referred to both sciatics. At first I was deceived into treating him for sciatica by vigorous local measures, including the actual cautery. In time I found that his sciatic pains were too paroxysmal and shooting in character to correspond to local neuritis, and, moreover, that the characteristic tenderness on pressure along the course of these nerves if inflamed was not, in him, at all well defined. Meantime he had a fixed pain in the back, just above the lumbar vertebræ, nothing like as severe as in the legs, but nevertheless both uniform and persistent. Months passed, and then the development of a soft swelling divided by Poupart's ligament in his right groin explained everything as due to the progress of a psoas abscess. I have always since searched for the abiding places of pain, no matter what its excursions might be.

When a tumor involves in its growth the trunk of a nerve, it sometimes causes trophic changes at the peripheral distribution of the nerve on the skin in the form of an intractable ulcer, or as an herpetic eruption followed by persistent local anesthesia.

Painful cramps are a variety of pressure pains. The cramps are always of reflex origin, and when persistent the tonic contraction causes much wasting of the implicated muscles. We have in the persevering use of the warm-water douche a specific remedy for both this pain and the muscular contraction which causes it. Pressure pains in general are much less under the control of opium than inflammatory pains. The pains soon get used, as it were, to the opium, and we have to increase the dose to get the desired effect. On the other hand, antipyrin, phenacetin, and the other coal-tar derivatives are often of considerable service, either combined with an opiate or with bromids. This is especially true in pains caused by aneurisms.

Stretching Pains.—The peculiarities of stretching pains are well illustrated during the passage of a calculus through the bile duct or the ureter; also, in severe sprains. More than any other pains, they, when severe, cause great faintness, nausea, and vomiting, often with chills and cold sweats. Unlike either inflammatory or pressure pains, their onset is usually sudden, and in the stretching of narrow ducts painful spasms in them so commonly develop that the attacks have a pronounced paroxysmal character, whence the name "colics" is derived. The sufferers show plainly enough by doubling themselves upon the affected part or by firmly pressing their hands over it that the pains are not inflammatory. Meantime the characteristic radiations of the pains are of much diagnostic value in distinguishing either hepatic or renal colics from each other and from other painful affections in the abdomen, being in the hepatic variety from near the umbilicus directly through to the back and upward between the scapulæ, and in the renal from the back down the groin, with retraction of the testicle, and radiated also to the inner aspect of the thigh. In sprains, at the onset there occurs a marked superficial tenderness of the skin, which, however, passes off in a few hours, but which may serve, at the ankle, for instance, to show that the injury is a sprain rather than a fracture. The pains of so-called myalgia, so common in women with feeble muscular development, felt at the attachments of the abdominal muscles to the ribs or along the attachments of the erectors of the spine, are virtually stretching pains due to an undue pull upon tendinous textures from deficient muscular support. Cutaneous hyperesthesia, therefore, is very common at the places where the pains are most felt, and the patients often complain of the wearing or exhausting nature of these pains, which, moreover, show that they are not properly neuralgic, from their having no tendency to shift. In the treatment of biliary or renal colics, the first indication is to prevent the spasms which induce the paroxysms of pain, and, moreover, hinder the onward passage of the calculus. This is best done by arresting the afferent impression of pain which evokes the motor effect of spasm, and we have nothing like a hypodermic of morphin, with atropin, for accomplishing this purpose. Next follows the excito-motor paralyzer, warm water. In biliary and renal colics the sudden cessation of pain generally indicates that the calculus has passed out of the duct, and hence is much more reassuring than sudden cessation of a severe inflammatory pain, for that may mean that gangrene has supervened. Sprains are best treated by douches, of hot water when acute, of cold when chronic. Local applications of belladonna or of stramonium ointments or liniments, with the addition of chloral, may relieve better than the lead-and-opium lotion so useful in inflammations. For the same reason belladonna plasters are beneficial in spinal myalgia. In myalgia, however, the first indication is to develop and strengthen the muscles by massage, or by alternate exercise and rest, combined with the great restorer of weakened muscles, the oxygen of the open air.

Neuralgic Pains.—There is no term which needs definition more than that of neuralgia. Etymologically, it may apply to any pain in a nerve, and hence we find it given to the most diverse kinds, from tic-douloureux to the pains caused by tumors. It ought to be cleared of all such vagueness of meaning, because true neuralgic pains have a wholly different causation from either inflammatory, pressure, or stretching pains, and hence demand different treatment. Thus, in the first place, they present none of the signs of inflammation, no rise of temperature, no swelling or local infiltration, no objection to pressure, but the reverse, likewise none to movement, but often here also the reverse, and they are not accompanied by any characteristic disturbance of function in the parts which they affect. On this account we would not include among the neuralgias typical cases of tic-douloureux, or the so-called trigeminal neuralgia, because in this affection the paroxysms of pain are particularly excited by the functional movements of the facial muscles, such as in chewing, opening the mouth for speaking, or even by the movements of facial expression or emotion, etc. Moreover, whenever the affected branches of the trigeminus are superficial enough for us to press upon them we find them exquisitely tender, as at Valleix's points. The view that this affection is a true neuritis of the *nervi nervorum* has much in its favor, and the effects of treatment further confirm this supposition. The same may be said of most cases of so-called brachial neuralgia, where the arm has to be kept as still as the leg in sciatica to prevent the paroxysms of pain. Likewise most cases of "cervico-occipital neuralgia" are really cases of neuritis, and should be treated accordingly.

Unlike inflammatory, pressure, or stretching pains, neuralgic pains are much less local, and many of them are prone to wander about. This feature alone may serve to demonstrate their nature, for frequently they shift their seat altogether, wholly disappearing from one locality to develop with just the same symptoms and severity in quite another part. In this respect they are readily distinguishable from the pains which radiate from an inflammatory or pressure focus. The grand distinction of neuralgic pains, however, lies in the significant fact of intermittency. Neither an inflammatory, or a pressure, or a stretching pain can intermit; they can only remit, or else cease with the cessation of their cause. Neuralgic pains, on the other hand, come and then go entirely, leaving the patients as free from them, temporarily at least, as if they had never experienced them. No one, for example, can foretell that the vivacious lady whom he meets in company will be entirely prostrated the next day with a severe sick-headache, and then two days afterward be as free from it as ever. This fact about many neuralgias is very suggestive of their toxic origin, for it is only in chronic toxemia that we have similar cumulative results leading to nervous explosions, so to speak, as, for instance, uremic convulsions or attacks of gouty asthma.

We would divide neuralgic pains into the febrile toxic, and non-febrile toxic. Examples of the first are found in the aches produced by the poisons which cause fever. Frontal headache, lasting for more than twenty-four hours, and accompanied by a rise of temperature, with a general aching in the back and limbs, should lead us at once to suspect a febrile infection. If it lasts three days or more, it must be due to such a cause. These pains are in no sense inflammatory, for they cause great restlessness, the patients tossing about in bed on their account, and not on account of the fever. Though in most specific fevers these headaches last longer than most neuralgic pains, yet they always cease before the fever ceases. The best medicinal remedies for them are phenacetin with ammonium bromid, or, in epidemic influenza, phenacetin with aconit and a small dose (one grain) of Dover's powder. Also, cold applications to the aching head are often very grateful.

The second class of toxic neuralgias are the non-febrile, of which a good example is found in the truly periodical neuralgias, or those which come on at definite times of the twenty-four hours, and then subside like an attack of ague. It is natural, therefore, to surmise that they have some connection with malarial infection, but in many cases this is not plainly demonstrable, and, moreover, notwithstanding they may be very severe, they most commonly are not accompanied by rise of temperature. They may attack the head, the sides of the chest, or abdomen, or be located anywhere along the spine or in the pelvis. I have not met with more violent cases of pain than in some of these patients whom I have seen both in my own practice and frequently in consultation. In the latter cases I have learned that quinin, Warburg's tincture, arsenic, and the coal-tar analgesics had been previously administered, often in heroic doses, without any effect toward preventing or mitigating the attacks, and hence I am glad to say that I consider ergot in full doses to be a true specific for periodical neuralgias, whatever their seat be. A drachm of the fluid extract should be taken every two hours, with a drachm of elixir of cinchona in water to prevent nausea. If the stomach does not tolerate the ergot it may be administered per rectum in two ounces of water. The first dose should be taken at the very beginning of the onset of the pain, and if that suffices to arrest it a second dose is not needed, but with some it requires three doses. It is curious that in many cases I have found that twelve grains of quinin will cinchonize patients who have just taken ergot when doses of thirty grains taken before had not done so.

Migranous headaches I regard as essentially toxic in their origin and due to perversions in gastro-intestinal digestion, causing absorption into the blood therefrom of poisons which at a certain point of accumulation bring on the attack. Like gouty or lithemic derangements, they are very commonly due to constitutional or hereditary tendencies. Ergot is here also a specific for the attacks themselves, administered as above recommended for periodical neuralgias, but in many cases we may succeed as well with ten or fifteen grains of antipyrin and a teaspoonful of aromatic spirits of ammonia, taken early with the first symptoms, when the patient should at once lie down, and then repeat the dose in two hours if required. But the true treatment of migraine is prophylactic, by a prolonged and systematic course of intestinal antiseptics.

Patients with a persistent rapid action of the heart, without fever and without cardiac or renal disease to account for the tachycardia, are very commonly great sufferers from neuralgic pains in the various parts of the body. This is well shown in many cases of Graves' disease, both before and after the development of thyroid symptoms, but such neuralgias may be equally present in patients with such tachycardia who never show either exophthalmia or goiter. Here intestinal antiseptics, such as weekly mercurial purgation, perseveringly followed up by phenol or naphthol bismuth, bismuth salicylate, strontium salicylate, salol, etc., and total abstinence from butcher meat, taking milk instead, will cure both the neuralgias and the over-action of the heart.

Gastric acidity is apt to produce frontal and temporal headaches, while occipital headaches, accompanied by tenderness on pressure upon the eyeballs, are distinctive of intestinal fermentation. In some cases severe attacks from like causes take place in the stomach, which go by the name of gastralgia. The relief following upon the administration of $\frac{1}{20}$-grain doses of arsenious acid in gastralgia would seem to indicate its causation, for arsenic very quickly arrests any form of fermentation.

Under the head of non-febrile toxic neuralgias would come those occasioned by chronic metallic poisoning, especially that by lead, in which wandering pains occur which are apt to be mistaken for rheumatism, though undoubtedly they have more relationship to gouty neuralgias, as lead poisoning is one of the recognized causes of the gouty state. On the other hand, the abdominal cramps are just as specific effects of plumbism as its special paralyses are. Lastly, among these non-febrile toxic neuralgias we should not forget those due to Bright's disease and to diabetes. Pain in the back of the head is common in Bright's disease, and is not necessarily of dangerous import. Not so, however, when general pains are complained of in every part of the body, for these may presage a near fatal issue, as their frequent association with convulsions shows. On the other hand, the local pains occurring in diabetes not infrequently are due to actual neuritis.

The third class of neuralgic pains are the non-toxic. They sometimes appear to be purely reflex, as, for example, a true trigeminal neuralgia caused by a necrosed piece of bone in the nares and which is cured by its removal. Under this class also come headaches from eye strain, about which we hear so much. Of one peculiar form of headache I have met several instances. The ache seems to begin at the root of the nose, and pass horizontally backward to the occiput. It is always aggravated by prolonged bending forward of the head, as in writing, etc., and has a special tendency to cause incapacity for mental exertion. In each of my cases it was found associated with a nasal obstruction from old fractures of the nasal bones, and the headaches were cured by operation.

One important form of neuralgic pains of a non-toxic character are those due to degenerative processes set up in sensory nerves and nerve-roots, such as the lightning pains of tabes. The degenerative processes themselves may have been due originally to a toxic infection, such as syphilis, but this no longer operates as a cause of the pain. That these pains are not peripheric is shown by their contrast to the peripheric pains of tic-douloureux, for in the latter the peripheral nerves are exquisitely tender, while in tabes the skin area of distribution of the affected nerves is anesthetic. The patients rub, seize, or grab the affected part as if they were desperately bent on arresting the pain in its flight. For the pains of tabes the coal-tar analgesics are often very effective, particularly acetanilid. Nitrate of silver also often affords decided relief, and it is curious that this drug will sometimes unmistakably mitigate pressure pains caused by a tumor involving the roots of a spinal nerve, as I have had occasion to note in several instances.

I surmise also that the rapidly fatal form of angina pectoris is likewise due to degenerative disease of the intrinsic cardiac nerves. Some writers seem inclined to merge this most specific disease of angina pectoris into a mere general symptom, and to confound with it all forms of cardiac pains not due to inflammatory processes. Thus the paroxysmal anginose pains in a case of combined aortic stenosis and incompetence are pronounced indistinguishable from those of angina pectoris. Let the mitral valve, however, begin to leak also in these cases, and so relieve the intraventricular pressure, and the pains vanish altogether. I cannot but regard them, therefore, as wholly analogous to the cardiac pains in patients with general arterio-sclerosis and high-tension pulse, and which are brought on by overwork of the heart muscle, just as cramps may be induced in the calves of the legs by too prolonged dancing. But the clinical histories of typically fatal attacks of angina pectoris are totally different. Thus one of my patients who had never experienced a single symptom of heart trouble before, was suddenly attacked on waking in the morning, while resting quietly in bed, with the first pang, which so terrified her with a sense of impending death that she sent for me. I saw her three hours afterwards, when she was quite free from pain, and when she gave me a most intelligent account of it. I advised her to remain in bed, and left a prescription for amyl nitrite, to use in case of a return of the pain. Ten minutes afterward she suddenly died. Another was a gentleman who, without any previous warning, was first seized with a short paroxysm while talking to a friend. I saw him soon afterward, and his description of the attack left no doubt of its nature. Ten hours afterward he had a second attack, and died instantly. Now, these cases, and others just like them, in my experience, have this feature in common: that the patients had had no symptoms whatever referable to the heart before these capital ones, and therefore are no more to be confounded with the every-day cases we meet of anginose pains from cardiac inability to cope with the task of the circulation than the muscular movements of epilepsy are to be confounded with those of chorea. A painful cardiac affection which has often visited a patient, especially after exertion, may at any time suddenly end his life, but its repeated visits and their connection with causes of circulatory strain point more to disorders of a muscular kind in the heart than does this dread malady which needs strike only once or twice. In the second case, just related, the most careful macroscopic and microscopic examination of the muscular and vascular textures of the heart failed to show any deviation from health. I regret that our modern methods of examination of nervous tissues were then not known, for I think that the cardiac ganglia might have shown degenerative changes which would justify us in speaking of "cardiac crises" as we do of gastric or laryngeal (bulbar) crises in tabes.

Anemia is often stated to be a cause of neuralgia. I would rather say that neuralgic pains are very common in anemic patients; but that anemia *per se* causes neuralgia I doubt, because of its frequent absence in many of the worst cases both of primary and of secondary anemias. Thus I have met with instances of pernicious anemia in which there was no neuralgia complained of from the beginning to the fatal end of the disease. On the other hand, blood impoverishment is often the direct result of the toxemias, which also cause toxic neuralgias, and hence I would paraphrase the saying that "neuralgia is the cry of the nerve for more blood" into a cry for purer blood. Iron, cod-liver oil, etc., are good remedies in these cases by improving that general nutrition, which is nature's most effective antiseptic.

Subjective Pains.—In a sense all pains are subjective, for if by severing the nerves we interrupt the conduction to the sensorium of the severest inflammatory or pressure pain, there will then be felt no pain at all. But as the sensation of pain itself is a centric function, why may its origin not be in a disturbance of the pain centers themselves without an antecedent peripheric irritation? Certainly we must admit that, for example, in many cases of hysterical hemianesthesia this sensory derangement evidently starts from a cortical area, but if so, then a hyperesthesia amounting to severe pain is just as likely to own a similar origin. I have no doubt that this is sometimes the case also in patients who cannot properly be termed hysterical, but who are said to have a highly nervous organization, and in whom some violent attacks of pain are brought on by strong emotion. The cerebral relations of these pains, however, make them so likely to be influenced by purely cerebral states, being often both induced and removed by mental impressions alone, that we are apt to regard them as more or less imaginary. This, however, is a less common mistake now than formerly, as the pathology of hysteria itself is becoming better understood. A motor paralysis of hysterical origin is as real as any other paralysis, as in the case of a motionless vocal cord in hysterical aphonia, where, of course, the patient knows nothing about the paralyzed part which she has never seen. Likewise hysterical pains may be as unimaginary as such motor derangements are. Owing, however, to their cerebral origin, they are far more intimately associated with mental or emotional states than is possible with any other class of pains. The patients think them, so to speak, as much, if not more, than they feel them, and so are often led to refer them to any part of the body by simple mental suggestion, or what amounts to the same thing, forgetting one pain while their attention is directed to another. Hysterical pains, therefore, may simulate all varieties of pain, one after the other, in such succession that a beginner in practice may be much puzzled by them, especially when complained of about the joints or in the abdomen. Hence, a careful observation of the mental accompaniments of the pain is the surest way to arrive at the diagnosis of its hysterical nature. Thus real objective pains are very concisely described, with a few characteristic gestures and equally few words. Subjective pains, on the other hand, are described with many a theatrical gesture and with a copious variety of terms, which all go to show how much the patients occupy their minds with dwelling upon them. This of itself is enough to strengthen the presumption of their subjective character, for objective pains always inhibit both thought itself and its expression. The description of a lively disturbance in the great toe by gout is generally limited to interjections or expletives, while, on the contrary, the hysterical patient seems to enjoy talking about her unexampled sufferings by the hour, especially to a sympathetic listener. The treatment of hysterical pains is to be that of hysteria itself. Nothing is more useless or mischievous than to relieve them by anodynes, and particularly by opiates.

Cutaneous Reflex Pains.—Dr. Henry Head, Registrar of the London Hospital, has directed the attention of the profession to a very interesting class of pains which are elicited by lightly pressing the skin, or touching it with the head of a pin. Nothing therefore could be so extremely peripheral as these pains, but their interest lies in the fact that only deep-seated visceral disease will cause them. When these pains are produced by the light application of a large-sized pin's head, the patient not being allowed to see it done, they are complained of as a burning or smarting sensation, which when pronounced leads the patient to beg that the experiment be not repeated. I have myself repeatedly confirmed this curious phenomenon. Thus a man with a calculus in the left kidney always swore when the pin's head touched the tip of the left twelfth rib. The special interest of Dr. Head's researches lies in his demonstration of the definite limitation of the cutaneous areas of these pains to the distribution on the skin of nerves associated with the nerves of corresponding internal organs. This distribution is not according to the segmental distribution of the spinal nerves, but according to certain definite associations of nerves which are curiously illustrated by the eruptions of herpes zoster, which Dr. Head shows, correspond to the different cutaneous areas of reflex hyperesthesia in organic visceral disease. Thus I found in a patient with gastric ulcer these well-marked cutaneous pains over the ensiform cartilage, at the junction of the eighth rib with its cartilage, and in the back on a level with the angle of the scapula. Dr. Head has mapped out a most elaborate delineation of the areas on the skin, in which, if these pains are present, we may thus diagnose from what internal viscera they proceed, but we cannot more than allude to them here on account of the need of constant reference to his charts to illustrate the statements which he makes. In trying, however, to verify these observations myself, I have found that when these pains are present in the specific localities which he describes, they afford very valuable indications, but their absence is no proof whatever of the absence of organic visceral disease. Thus, only about one out of eight cases of undoubted ulcer of the stomach showed these painful skin symptoms, and then not unless the local pain in the stomach itself was well marked. Similarly in heart disease, aortic aneurism, and other internal affections, the pain thus reaches the skin only when it first has been severe within. Nevertheless, it is a very suggestive subject and merits further investigation, not only for the aid which it may afford in the diagnosis of internal organic disease, but also in the relation of many pains about the head which have been classed as local neuralgias, but which may thus be shown to be associated with definite disturbances, sometimes functional as well as organic, in the thoracic and abdominal viscera.

THE DIFFERENTIAL DIAGNOSIS OF "NEURASTHENIA" AND ITS TREATMENT.

BY ELMORE S. PETTYJOHN, M.D.,
OF ALMA, MICH.

EVER since Beard used the term "neurasthenia," and Van Dusen directed attention to a group of symptoms so named, the profession has been struggling to settle upon a definite set of symptoms to be thus classified, and, in my opinion, has as yet but poorly succeeded. Althause of London protests against the term, and Gowers says that "nervousness" covers the conditions. Different writers give different illy-defined symptoms, and subdivide them as being of cerebral and spinal origin, some even finding varied local conditions which they denominate neurasthenia. There is one thing they all agree upon: that this group of symptoms indicates disease of some or every part of the nervous system, or a marked defect in the nutrition of the cerebro-spinal axis, giving an almost endless variety of symptoms most difficult to classify.

The changes noted in the patient come on gradually. There is exaltation and depression in alternate waves, each change lasting from one to three weeks, and often being poorly defined; a morbid watching of himself regardless of the experience of others; a disinclination to see a physician; the firm belief that he will not recover; lack of desire for occupation; lack of ambition; nervousness in the presence of others, and avoidance of society. He has a tired feeling, or at least the absence of the feeling of conscious well-being, and disturbance of vision, insomnia, and loss of power to direct attention to anything for any length of time. In nearly every case some delusion will be found referable to the region of the spine or chylopoëtic system, or an unreasonable belief that there is some morbid condition of the body which no one can understand or explain. Society and the members of his family are repulsive to him. As one set of symptoms of an exaggerated or depressed condition of things disappears another takes its place, until almost the whole curriculum of symptomatology is manifested. Nervousness, weakness, insomnia, headache, neuralgia, vertigo, exaggeration, and depression, with local anesthesia and hyperesthesia over the spine (more frequently the latter), and the multiplied expressions of the disturbance of the integrity and equilibrium of the nerve centers may be met with.

The appetite is poor, the tongue coated, the breath fetid, the bowels constipated. The skin is dry or excessively moist, with lessened reaction after cold bathing. Sleep is broken, and even if the patient sleeps a sufficient number of hours, he is not refreshed. He is over-sensitive to noise and cannot endure even rhythmical sounds. He is nervous and restless, and the little things that were formerly unnoticed are now very annoying and burdensome. He is excessively fastidious as to cleanliness of person and surroundings. Instead of appearing anemic, the patient is as often of full habit and has a ruddy color, the number of blood corpuscles and the hemoglobin being normal, as demonstrated in a large number of cases I have examined. The urine is of low specific gravity and contains a large amount of phosphates and oftentimes some sugar or albumin. In some cases we find a combination of all these elements. If the medulla is affected we almost certainly find sugar and, if impaired kidney-nutrition, we would find albumin. All this means that from lack of eliminative power the system reabsorbs from the blood its own ptomains and there occurs a form of auto-intoxication which, leading to or combined with malnutrition and expenditure of nervous force, produces this morbid state of the entire system.

These conditions must be distinguished from those found in the uric acid diathesis, with which many of these symptoms are associated. The whole train of symptoms is born of a lack of physical nutrition, and there is not one detail in all this varied category, so-called neurasthenia, which does not belong to and cannot be classified as hysteria, hypochrondriasis, or mild melancholia. Anemia of the cerebral cortex undoubtedly exists in these cases, although degenerative changes occurring in the vessels of the cortex from excessive use of alcohol or from specific infection may often present the same symptoms and the diagnosis is made only under treatment. Neurasthenia may be a convenient term with which to mollify the friends of the patient, but neurasthenia, as a distinct affection, in my opinion, does not exist. It is a popular term among the laity, and many a young woman has become a useless thing in the world of action because she thinks she has neurasthenia, or, as later termed, "Americanitis," which name I utterly repudiate. It is a matter for consideration as to how much physicians are to blame for encouraging this popular delusion, and whether we may not some day, on this very account, be accused of nursing patients instead of placing a veto on the laity-born, self-perpetuating fad, and letting firm-willed training-school graduates do the nursing. I believe we are to-day on the verge of a revision of our nosological nomenclature, and that diseases will hereafter be classified in accordance with their essential producing causes and not according to their symptoms. When this comes to pass the term "neurasthenia" will become extinct.

We are not content with the knowledge, secure or insecure, that we have gained, and while using it as best we may for the good of humanity we realize in all humility how much there is we cannot know, yet cannot doubt. Shakespeare asked, "Who can minister to a mind diseased?" I answer, "No one," but we can minister to the body and brain diseased, and that right well.

Omitting the etiology of these conditions of the nervous system in reference to congenital physical defects, and the effect of the toxic matter of alcoholic or specific origin, I believe these abnormal states may be expressed in one word, "Malnutrition," and, in turn, that this condition of the body is chiefly due to the lack of equilibrium between elimination and repair.

A continual procession of non-viable atoms is constantly penetrating living molecules where they are themselves converted into living molecules by assimilation, that undiscoverable power of living matter. Each complex living molecule by varied processes of endosmosis, exosmosis, and the chemical reactions with oxygen and other gases, is reduced to a dead or useless condition of matter, which is then eliminated to make way for the ingestion of other new nutrient atoms. *The systematic repetition of these processes is life and health.* When we stop dying (eliminating) we cease to live. While in health, so far as consciousness registers, these two processes are simultaneous; in a pathologic state of the body that is to be treated we would place elimination before repair. In a sound body there is a *complete balance of this double process of nutrition,* but when the equilibrium of exchange in these molecules of living matter is disturbed in nerve, muscle, or blood corpuscle we have a functional disorder, which, if continued, eventuates in a pathologic condition. To produce, or aid in producing, this double process and re-establish its balance is rational medical treatment. The alchemists believed that if some agent could be found to fix or crystallize the tissues in their full growth and vigor, decay would be impossible and youth would be eternal. We know that health is incessant change according to laws of metabolism, and that the extension of the period of vital energy, the expression of health, can only occur by that fine balance of waste and repair we call good nutrition.

I would mention treatment under three heads—elimination, food, environment. A systematic, scientific course of hydrotherapeutic treatment in addition to medication is, in my opinion, essential to the best results in these cases, particularly with reference to elimination through the skin. This is obtained by Turkish, electric, vapor, hot mineral, or fresh water baths (always with cold to the head), combined or alternated with wet hand, alcohol or oil rub, and faradization. All these treatments should be given by a trained nurse under direction of the attending physician. They may be given at the patient's home if he will take the trouble to attend to the details, and if the doctor gives explicit directions and instruction. If the patient is strong enough the entire body may be douched with cold water twice daily, provided a good reaction occurs, to stimulate the nerve centers to the greatest activity. The hot bath determines the blood to the surface by temporary inhibition of the vasomotor system dilating the capillaries, withdrawing the blood from the deeper tissues, causing perspiration and elimination direct, and at the same time temporary exercise and increase of nutrition of the skin. Rubbing is skin massage, faradization is a skin stimulant, both of which are exceedingly helpful aside from their soothing effect on the patient. I do not now speak of the induced current with the Tripier apparatus which affects the muscles and deeper tissues.

For elimination through the kidneys I prescribe a glass of some mild alkalin water agreeable to the stomach on arising, at 11 A.M., and 4 and 9 P.M., using in all eighty ounces of liquid daily, exclusive of that taken with the food. If the solids are in excess and the amount of urine is scant, I direct, in addition, that a pint or quart of ozonated lithia water be taken daily. A tenth-grain calomel tablet triturate at night and a salin laxative in the morning are given regularly as needed. Recumbent rest and active exercise are definitely prescribed in frequent alternations for every day with methodical regularity. Passive and resistive manual movements are ordered, and those of mechanical movement applicances also, when available. Walking, running, horseback-riding, cycling, tennis, or ball playing, or gymnasium practice, after anthropometric examinations, are prescribed. When the patient is too weak to be out of bed the induced current and massage are employed, the patient taking one treatment of each daily, properly graduated, in addition to some light form of hydrotherapeutic treatment. For stimulation of the nerve centers a hot fomentation to the entire spine, or the alternation of the fomentation and ice to this entire region, produces admirable results. The cold head bath with heat to the stomach, liver, and extremities, reduces cerebral congestion and determines the blood to the central organs, and is employed when advisable. The ice bag to the base of the brain is a better sedative than drugs. Wholesome, nutritious food should be taken at regular intervals of six hours, (during the night also if awake) in large quantities, whether or no there is an appetite. Appetite I believe to be largely a mental condition. Stimulating broths, but not solid food or milk, should be given between the intervals of regular meals. The stomach of even a sick person should have some rest. If there is difficulty of digestion the stomach contents should be examined and the lacking digestion factor should be supplied.

The patient's environment should be pleasant, agreeable, and often unhomelike. He should be mentally diverted and occupied, and at the same time he should be encouraged to make some effort to forget himself by thinking of something else, and taking an interest in others. The removal from care and responsibility, change of occupation (not idleness, though no set heavy tasks requiring much mental effort), living away from home and business scenes where association of ideas will bring a return of the morbid thoughts, are *essential* aids to recovery. Very many things can be done besides watching and feeding the patient. With the daily oversight, care, and direction of a physician experienced in the treatment of these cases, and the above indications intelligently carried out, the great majority of this class of patients, both chronic and acute, will recover, and many men and women will be saved from a life of misery and insanity in the present and in the coming generation.

THE PHYSIOLOGICAL ACTION AND THERAPEUTIC USES OF YEAST NUCLEINIC ACID, WITH SPECIAL REFERENCE TO ITS EMPLOYMENT IN TUBERCULOSIS.

BY VICTOR C. VAUGHAN, PH.D., M.D.,
OF ANN ARBOR, MICH.;
PROFESSOR OF HYGIENE AND PHYSIOLOGICAL CHEMISTRY IN THE UNIVERSITY OF MICHIGAN, AND DIRECTOR OF THE HYGIENIC LABORATORY.

(Continued from page 302.)

Review of Cases Reported in 1894.—Two years ago I reported twenty-four cases treated with yeast nucleinic acid.[1] At the time of that report twelve of these patients were living. It will certainly be of interest to give the further history of these cases, and this I will now proceed to do as briefly as is consistent with accuracy.

CASE II.[2]—I began treating this young man May 1, 1893. At that time "moist râles were heard over both lungs, both anteriorly and posteriorly. No cavities could be detected. The sputum contained numerous tubercles, which on being crushed and stained were found to be filled with bacilli. The daily maximum temperature for three days before beginning the treatment averaged 100.3° F. Night sweats were constant."

The treatment was continued through May and June of 1893. "The temperature did not reach 100° F. after June 2d; it seldom went higher than 99° F., and during the last four days of treatment it was normal continuously. Night sweats were occasional and slight during June. The cough and expectoration decreased, and some mornings during the latter part of June, he failed to raise anything when asked to bring the sputum for examination; but when the sputum was raised and examined the bacillus was always found."

In July, 1893, this young man went, by my advice, in a wagon from Kansas City to Boulder, Col., where he has continued his residence. He has had no medicinal treatment since going to Colorado. He considers himself well, but his weight is practically the same as it was when he was under treatment in 1893, and the sputum, a little of which is coughed up nearly every morning, contains from two to six bacilli in each field. I have not seen the patient since June, 1894, when a physical examination showed practically the same condition of the lung as that existing one year before, and consisting wholly of diminished resonance over both upper lobes.

From this case, I have drawn the following conclusions, subject of course, to revision, as all such conclusions must be, by future observations: (1) Physical examination of the lungs in tuberculosis shortly after a hemorrhage (this patient had a hemorrhage the day before the first examination) may give a very erroneous impression of the extent of the involvement. The moist râles heard over the greater portion of both lungs in the first examination of this case were due to the pneumonic infiltration induced by the hemorrhage, and the area of tubercular involvement was not so great as I at first supposed. (2) The sputum may contain tubercle bacilli long after the patient supposes himself well. This is certainly true when the disease has been arrested by residence in a favorable climate. This explains the frequently observed fact that consumptives apparently cured by long residence in a suitable climate suddenly develop an active and rapidly progressive form of the disease on returning to a less favorable climate; or the equally well known fact that such persons may remain in apparent health so long as they live out of doors, but soon die of tuberculosis on changing their occupation to one more sedentary, especially when a large portion of the time is spent under unsanitary local conditions.

---

[1] "Treatment of Tuberculosis with Yeast Nuclein," MEDICAL NEWS, 1894.

[2] Refers to number of case in first report.

Webber[1] gives the following interesting history of a tubercular family, which suggests the possibility of the tubercle bacillus remaining in an inactive state in the body for many years:

> "Thirty years ago I treated a woman in a small street in Bloomsbury Square for galloping consumption. Her husband, a teacher of languages, had died shortly before, at the age of thirty-eight, in the German hospital, of chronic tuberculosis. Both his and her family were tuberculous. They had seven children, one of which had already died of tuberculosis. Of the six remaining children all save the youngest, a rachitic boy, were apparently healthy. On the death of the mother, intelligent and well-to-do friends took the children to one of the most healthful parts of Germany and brought them up under the best hygienic conditions. The eldest son remained perfectly well so long as he lived out of doors, but at the age of twenty-three he became deeply interested in philological studies and worked day and night, confining himself to his study-room, in which he took most of his meals. Eighteen months later he died of quick consumption. The second son interested himself in agriculture until he reached the age of twenty-nine. Up to this time he apparently enjoyed perfect health. At the above-mentioned age he changed his occupation, and worked in an office, confining himself closely. Two years later he began to have hemorrhages and ultimately died of tuberculosis. The third son entered and continued in a cavalry regiment, and is the picture of health. The fourth child, a girl of five years of age at the time of the death of her mother, is now the healthy wife of a German farmer. The youngest son, the rachitic boy, is now a robust farmer in Manitoba, and the youngest daughter, also in perfect health, lives with her Canadian brother."

Of course it is possible that the first and second sons might have become infected for the first time after entering upon their sedentary occupations, but it is also possible that they might have carried the infection from their early childhood. The presence of living tubercle bacilli in calcified cavities in the lungs is mentioned in another part of this paper. The point which I wish to emphasize here is that one in apparent health may carry the tubercle bacillus in his lungs for many years.

Under date of November 1, 1896, this patient (Case II) writes me as follows: "I have examined my sputum and find b. tuberculosis in it in such small numbers that in a cover-glass preparation it takes a little hunting to find them. My general health is excellent. I spent the summer out of doors and climbed Long's Peak (14,270 feet) without difficulty."

CASE IV.—This was an aggravated case of urinary tuberculosis. Hypodermic injections of iodin and gold, and boric acid, salol, quinin and iodoform by the mouth, had been tried. One gallon of cod-liver oil was taken within seven weeks. The nuclein solution was administered hypodermically and also injected into the bladder. This treatment was begun in June, 1893, and continued for nearly one year. In November, 1894, the patient, a practitioner in Nebraska, reported no incontinence, scarcely any irritation of the bladder, and that he weighed more than he had for twelve years. No bacilli could be found in the urine. In March, 1896, he wrote me that he remained free from any evidence of a return of the disease, and that he had been engaged in a very laborious country practice. January, 1897, he reported himself as being perfectly well.

CASE V.—This was also a case of urinary tuberculosis of several years' duration. I closed my report on this case in 1894 with the following paragraph:

> "The greatest weight reached before the illness was 132 pounds. The decrease was gradual and constant to the time of beginning the treatment, when he weighed 114 pounds. Since that time there has been a steady increase, and the figure is now 138. The temperature at first often reached 102.5° F., sometimes 103° F. It has not been above the normal since early in October, 1894. The urine will be wholly free from sediment for several consecutive days, and then there will be a little pus in which the bacilli can be detected. There is still some undue frequency of micturition, and at times a sensation that the bladder has not been wholly emptied at the close of this act. The kidney has decreased in size, but is still abnormally large. There has been no pain from the passage of tuberculous masses through the ureter since the latter part of May, 1894. *Of course it is possible that the disease may extend again. I shall not call this a cure until the urine becomes permanently normal, and this may never happen.* But even should this not occur, the history of the case is unique."

The wisdom of the caution expressed in the sentences now italicized soon became evident. In the spring of 1895, this young man, notwithstanding the continued use of the nuclein, developed acute general miliary tuberculosis and, although he hastened to

---

[1] "Lectures on the hygiene and climatic treatment of chronic pulmonary phthisis" (German translation), p. 31.

Colorado, died within a few months. This is the most marked case of the temporary abatement and subsequent rapid spread of the disease under the continued employment of the nuclein that has fallen under my observation. The remedy lost completely its apparent value, and was wholly without effect. This case illustrates the relation between local and acute miliary tuberculosis and the inadequacy of the nuclein treatment in the latter.

Case VI.—This, the third case of urinary tuberculosis reported in my article of 1894, has continued without any evidence of the existence of the disease. Dr. R. remains well, is engaged in a laborious practice, and one year ago published an interesting report of his own case.[1]

Case XVII.—This man continued this treatment until February, 1895. I last saw him in June, 1895. At that time there was still a marked prolongation of the expiratory sounds over both upper lobes, and the afternoon temperature generally registered 99° F. His weight remained at 140 pounds, and he raised some sputum each morning, which contained a few bacilli. Since June, 1895, I have not been able to ascertain his residence, and consequently have no knowledge of his present condition. The conclusion concerning this case, as stated in my report of 1894, was as follows: "I believe that in this case the disease has been retarded by the treatment—I will not say arrested, because so long as the infection remains there also remains the probability that it may at any time become progressive."

As this was a colored man, living from "hand to mouth," I shall expect should I hear from him again, that the disease has progressed.

Case XVIII.—This was a patient with a cavity in the upper lobe of the right lung and an extensive tuberculous pleurisy on the opposite side. Germs were abundant in the sputum and some were present in the effusion drawn with a needle from the left side. Treatment was begun February 19, 1894, and continued to November 23d of the same year. During this time the young man continued his work as bookkeeper and general office boy, cleaning the rooms, etc., in a bank. The weight practically remained unchanged during treatment but the average temperature slightly increased and "judging by this more than by the physical signs, I think that the disease is slowly progressing." A few days after discontinuing this treatment the young man went to Colorado, but the progress of the disease continued and he died in September, 1895.

Case XIX.—This is a saleswoman in a dry-goods store. The weight had fallen from 148 to 115 at the time of beginning the treatment, January, 1894. There was bronchial breathing over the right apex and subclavicular area and moist râles over the upper lobe of the left side. "*The sputum was non-purulent but contained tubercle bacilli.*" The treatment was begun January 4, 1894, and continued daily until the middle of July of the same year, when it was given twice a week until the first of October, 1894, and then once a week until June, 1895, since which time no nuclein has been given. The germs disappeared in March, 1894, and whenever on account of cold there has been any sputum, it has been examined, always with negative results. The patient continues her duties as a saleswoman and the conditions under which she lives are highly unfavorable. It is of interest to state that she is the third among the women clerks in the same store known to have developed consumption in the past six years. I have recently examined her lungs and fail to find any evidence of disease. Her weight varies from 125 to 135 pounds. This I have regarded as practically a case of unmixed infection. For two and one-half years the germs have not been found.

Case XX.—In the report of 1894 I stated that in this case the tubercle bacilli had not been found in the sputum since the last of March of that year, but that the tubercular cervical glands remained enlarged. This young lady continued under my charge until May, 1895. At that time her condition remained the same practically as stated in my last report. About this time her betrothed died very suddenly of appendicitis and since then the young lady has refused to take further treatment. Shortly after this I was called to see her on account of a pulmonary hemorrhage. I have examined the sputum and the blood and found the bacilli. She has been to my office a few times since and I have examined her lungs. The disease is slowly progressing. She still refuses further treatment.

Case XXI.—I last examined Mrs. M. in September, 1895. At that time there was no evidence of any disease in the lungs. She had no cough, and was, so far as I could ascertain, in good health. I have not seen her since that time, but she remains apparently well, and wholly free from cough.

Case XXII.—In this case the sputum was abundant, but non-purulent, and contained only a few bacilli. The bacilli disappeared in July, 1894, and none have been found since. Mrs. R. has borne one child since my last report. Her weight is now 128; at the time of beginning the treatment it was 106. Her work renders her susceptible to frequent attacks of acute nasal catarrh, but her lungs have remained free from involvement. This case illustrates what may be done even under adverse conditions, in the treatment of tuberculosis so long as it remains an unmixed infection.

Case XXIII.—Mrs. C. continues in good health, weighing 135 pounds. She has had no treatment and no cough since the summer of 1894. She is the wife of a poor farmer and the mother of ten children. This is another illustration of the good that may be accomplished by treating the disease in its earliest stages.

Case XXIV.—E. H. went to Colorado in November, 1894, and I am told that he continues well there. I have no more definite information concerning him.

Summary of the Cases Reported in 1894.—In my article of two years ago I reported twenty-four cases of tuberculosis treated with yeast nucleinic acid.

---

[1] *Therapeutic Gazette*, October 15, 1895.

Many of these were in the last stages of the disease when the treatment was begun. For details I must refer readers to the article. At the time of the report twelve (fifty per cent.) had died. Of the twelve then living, two have since died of tuberculosis (Cases V. and XVIII.). Of the others, three (Cases II., XVII., and XX.) are certainly still infected with the disease. Of the seven others, I have recent knowledge of five (Cases IV., VI., XIX., XXII., XXIII.), and these now show no evidence of the disease. So far as I know, two others (XXI. and XXIV.), remain well. This gives 20.8 per cent. known to be free from the germs for the past two years, and 29.1 per cent. counting the two who were free from the germs when last examined. It will be seen that these percentages are figured on the twenty-four cases, many of which were in a hopeless condition when first seen.

Case XXV.—Miss E., a student, has been under my observation since first coming to the University, in October, 1892. Her history is briefly as follows: Her father died at the age of sixty-seven, after suffering for some months from cystitis. (There is a possibility that the affection of the bladder may have been tubercular.) Her mother is living and well. Mother had one sister and one brother die of consumption. She has four brothers, all of whom are well with the exception of one who has some irregularity of the action of the heart, supposed to be due to the excessive use of tobacco. She has one sister, who is well. She knows of no special exposure to tubercular infection. During the first two winters of her residence in this place she suffered from frequent attacks of subacute bronchitis, coughed much and raised abundantly. In the spring of 1894 this cough was very persistent, and I several times examined the sputum, but with negative results. In June, 1894, she went to her home in Iowa, and apparently improved much. For some reason she delayed her return to the University in the fall, and was still in Iowa when she was attacked as herewith described: About 4 A.M., October 16, 1894, she awoke in an extremely nervous condition, and soon began to suffer from a severe cutting pain in the region of the left kidney. This pain soon became paroxysmal and excruciating. A physician was summoned and administered one-fourth of a grain of morphin hypodermically. This was followed during the day with repeated doses of chloranodyn, the pain continuing, but partly subdued by the medicines. Vomiting, possibly due to the anodynes, occurred in the afternoon. During the night she had a high fever, and her side remained sufficiently sore to keep her in bed for six days, and indoors four days longer. When she began to walk, she noticed that for some days every unexpected jar caused pain over the left kidney. Four weeks later she had a second similar, but less severe attack. After this she started on her return to Ann Arbor, but was compelled to stop for four days on the way on account of the pain in her side. This pain now returned daily, and was sufficiently intense to lead to the use of morphin. On November 27, 1894, this lady came to me and, after hearing the history of the attacks, as stated above, I did not doubt the correctness of the diagnosis of the Iowa physician, who had pronounced it renal calculi. I examined the urine, and was much surprised to find in it numerous tubercles, some quite as large as peas, rolled up, as it were, in epithelial cells. These contained bacilli in great numbers, and guinea-pigs inoculated with them developed tuberculosis. The urine contained no pus, blood, or albumin. Evidently the paroxysmal pains had been caused by the passage of these tubercular masses down the ureter. Nuclein injections were begun immediately, and continued daily for six months, then two or three times per week for another six months. Since October, 1895, no treatment has been given. The injections were made deep into the muscles directly over the affected kidney. The renal pain became gradually less pronounced, and the urine has been found to be constantly normal since June, 1895. The patient passed through the winter of 1895 and 1896 without any of the "bad colds" which had been so frequent and persistent during the winter of 1893 and 1894.

Case XXVI.—Mrs. W., of Marshall, Mich., came to me in October, 1894. She had several small cavities in the upper lobe of the right lung and there was only bronchial breathing over the corresponding lobe of the left lung. The larynx was involved and deglutition painful. Her weight was 116. An unfavorable prognosis was given and treatment was begun under protest. This patient has been most faithful and persistent in her endeavors to carry out the advice of her physician in every respect. With the exception of cocain in spray and lozenges for the throat, nothing but the nuclein has been employed. For one year the injection was given every day. At the expiration of that time, I insisted that the treatment should be discontinued for a time, but the patient felt that she was losing ground without it, and since then she has had injections nearly every day. She has kept a record of every treatment and has missed it only twenty days in two years. The weight has increased and during the past year has varied from 126 to 132 pounds. The condition of the larynx is much improved; deglutition is painless, and the urine normal. The cavities remain practically unchanged. I examined this lady November 12, 1896. The left lung reveals no abnormality. The breathing over the right apex and subclavicular area is bronchovesicular. I do not think that I am attributing too much to the action of the nuclein when I say that it has retarded the progress of the disease. Indeed, her condition is much better than it was two years ago. The temperature for the first year of treatment seldom had a maximum for the day less than 101° F. The maximum from September 17 to September 28, 1896, was 99°; from September 28th to October 2d, 98.3°; from October 2d to October 9th, 98.4°. It has been taken four times a day every day for the two years.

Dr. Foote of Marshall has been associated with me in the treatment of this and the following case. The patient now raises but little, but bacilli are present.

CASE XXVII.—Mrs. T., of Marshall, Mich., was first seen in December, 1894. Two brothers and one sister died of consumption. Patient has always had enlarged cervical glands. She lived in the same house with her consumptive sister during the illness of the latter. Patient has coughed for fifteen years, but this cough has been more constant for past six months. At the time of examination she was raising freely. Bronchial breathing and moist râles were heard over both upper lobes, showing that the area of involvement was large; but there were no cavities and the bacilli were found only after most minute search and frequently samples of sputum in which no bacilli could be detected were examined. This patient continued the use of the nuclein to June, 1895, when she had gained some ten pounds in weight and coughed much less. In the fall of 1895 the cough returned and she went to Florida. Dr. Foote writes me that this patient continued to improve so long as medicine was administered, but that she returned from the South with the disease much advanced and that he now regards her condition as hopeless.

CASE XXVIII.—Mrs. K., of Holland, Mich., aged forty-four, was first seen December 5, 1894. Father died at sixty-five with some obscure trouble not named by the physician in attendance. Mother died at fifty-six of consumption. Brothers and sisters have been free from tuberculosis. One of her mother's sisters and one of her father's brothers died of consumption. Patient has been coughing and raising for past three years. Some three weeks ago she went to Dr. King of Grand Rapids, who examined sputum and found tubercle bacilli. There is bronchial breathing over both upper lobes. The apices are retracted and there are probably small cavities in left lung. The afternoon temperature for three successive days before beginning the treatment averaged 101.5° F. This patient remained with me only three weeks. Since then she has been under the care of Dr. Kremers of Holland and Dr. King of Grand Rapids.

Dr. King sends me the following notes of this case:

1895. January 24. Returned from Ann Arbor, where patient had been under the care of Dr. Vaughan, who had employed nuclein solution hypodermically. The examination of the chest was made with much the same result as upon first examination, with exception that *moist* gurgling râles could now be heard at the left apex and bronchial breathing at the internal borders of both scapulæ. Cough and expectoration very slight. Appetite and digestion poor. At twelve o'clock noon, pulse 100; temperature, 99° F.

Patient placed upon "phospho-albumen," ʒ ii t.i.d., and benzoate of guaiacol, gr. iii t.i.d. Evacuant mixture when necessary for bowels; 70 minims one per cent. nuclein solution hypodermically, daily.

October 21st. Patient has been steadily improving. The treatment has been continued, and in addition, inhalations of creosote, eucalyptus and menthol are employed daily. At five o'clock P. M., temperature normal; pulse 100.

October 26th. Nuclein solution increased to 100 minims daily.

November 5th. Intercurrent "cold." Patient not so well.

November 10th. Improvement. Patient returned to Holland and the injections continued daily by husband.

1896. March 7th. Patient has been steadily improving in general condition. The areas of dulness have not increased and the râles, dry and moist, are entirely absent. For the past two weeks the nuclein solution one per cent. has been increased to 200 minims daily with good effect.

May 6th. Examination discovers no material change since March. About one week ago slight bloody expectoration; none since, however.

June 28th. The five per cent. solution of nuclein substituted for the one per cent., in daily hypodermic injections of 30 to 50 minims.

July 31st. Patient caught cold from exposure; increase of cough and expectoration.

August 5th. The five per cent. solution has been used continuously since June 28th, with success, although patient has not been quite so well as before the middle of July.

October 9th. The five per cent. solution has been continued, at times increasing the dose to 100 minims, with steady improvement. The areas of dulness are unchanged. There has been no extension of consolidation, and the patient enjoys comparatively good health.

The result up to date is eminently satisfactory to both the patient and myself.

(To be continued.)

CLINICAL MEMORANDUM.

EXCISION OF THE COCCYX FOR FRACTURE AND NECROSIS, WITH A REPORT OF FOUR CASES.[1]

By EDWARD NICHOLAS LIELL, M.D.,
OF NEW YORK;
LECTURER ON GYNECOLOGY AT THE NEW YORK POLYCLINIC;
VISITING GYNECOLOGIST, ST. ELIZABETH HOSPITAL.

IN fracture of the coccyx we have as etiological factors a blow or a fall, the tip of the bone usually receiving the impress direct. Parturition, more particularly when attended by a narrowed pelvic outlet, may also be ascribed as an occasional factor. The pain, acute at the time, frequently diminishes to such an extent that the patient often gives but little heed to the injury; but months, or perhaps years, later she consults a specialist, and it is found that often there is necrosis of the bone, with accompanying suppuration, the fistulous opening being usually over the sacrum, rarely into the rectum.

---

[1] Read by title at the ninety-first annual meeting of the New York State Medical Society, Albany, January 28, 1897.

Our attention is called to the condition of coccygodynia, a term applied without reference to the exact lesion present (there often being a concomitant pelvic lesion) by the patient complaining of pain in the region of the coccyx, which is decidedly increased when assuming a sitting position, or when sudden pressure is made upon the coccyx from any direction. Contraction of the attached muscles also gives rise to excruciating pain. The coccyx can readily be palpated and a diagnosis of fracture or of abnormal sensitiveness be made by means of the index finger in the rectum and the thumb over the region of the coccyx externally.

Measures for the relief of this condition should be of a radical character, temporizing being of no avail. Subcutaneous tenotomy has been suggested for this purpose, and has occasionally been resorted to, but it is an unsatisfactory procedure, and has deservedly been abandoned, since in nearly every instance a fracture, not infrequently attended by necrosis, is present. Excision of the fractured or necrosed portion of the bone is unquestionably the only measure to adopt, as by this means an excellent result and permanent cure is obtained. This operation, though not a difficult one, is by no means a simple procedure, as care must be taken not to injure the rectum, the septum being often thin and delicate. An incision, one and one-half or two inches in length, is made along the line of the coccyx and, if need be, extended over the lower portion of the sacrum. In severing the muscular attachments and dissecting out the portion of bone to be removed, I prefer blunt-pointed scissors and the handle of a scalpel. The fractured portion of bone can then be readily dislocated, either by the scissors or a small rongeur forceps. The stump of bone should then be rendered smooth and free from spicules; if necrosis be present, the bone should be thoroughly scraped. If the fracture is an uncomplicated one, and the operation thoroughly aseptic, the incision may be closed by suture; but in the case of necrosis, suppuration being present, only the upper portion of the wound should be closed, the remainder being packed with iodoform gauze. The dressing should be renewed every two or three days until the wound has entirely healed.

CASE I.—J. K., aged twenty-three, married seven months. Had a miscarriage three months after marriage. About one and one-half years previous to the time I saw her she had met with an accident, the lower portion of the spine having come in violent contact with a window-sill. She experienced acute pain, and shortly afterward an abscess developed at the site of the injury. This broke spontaneously and then closed, but during the following three months twice recurred, and was opened. At the time of my visit the abscess was discharging, the patient could not sit squarely, and an attempt to rise was accompanied by intense pain. The bowels were regular, and defecation was not painful.

A diagnosis of fracture of the coccyx, with accompanying necrosis, was easily arrived at, a probe passed into the cavity detecting the presence of exposed and roughened bone. The fractured portion of the coccyx was removed, the remaining stump thoroughly scraped, the indurated and necrotic tissue in the neighborhood of the sinus excised, and the wound packed with iodoform gauze. Recovery was complete.

CASE II.—B. T., aged thirty-four, married sixteen years. Had had one child, the labor being normal. Twelve years before she had received a kick on the lower portion of the spine, but the constant pain from which she was suffering at the time I saw her had not developed until several years later, since which time it had gradually increased in severity, especially when she walked upstairs, bent over, or defecated. The diagnosis of fractured coccyx was made, the fragment excised, and the wound closed with catgut sutures. Primary union took place, and there was no return of the trouble.

CASE III.—M. K., aged twenty-four, single. During four years she had suffered from a constant, dull, heavy pain in the region of the coccyx, which extended to the left hip and down the left thigh. She had met with an injury some time before, a closing door striking her as she was bending forward, in the neighborhood of the sacrococcygeal articulation.

The operation disclosed a rare condition of affairs, the coccyx presenting a double fracture, one being at the junction of the two bones and the other near the tip. Recovery was complete.

CASE IV.—M. S., aged twenty-one, single. This patient gave a history of having sustained a fall upon the end of the spine about six years previously, a chair having been pulled away as she was about to seat herself in it. She felt a sharp, stinging pain at the time, but this soon disappeared. Four and one-half years subsequently an abscess developed at the seat of injury. This had been opened by a physician, but a suppurating sinus three inches in length, its opening being one inch to the left of the sacrum, had persisted.

The operation for relief of the condition disclosed the presence not only of a fractured coccyx and considerable necrosis, but of a broad sinus, having four ramifications, two of which led into the deeper tissues. A mass of indurated tissue the size of a closed fist was excised, along with the fractured portion of the bone, and the wound packed with iodoform gauze. Two months elapsed before the wound had entirely closed.

HOSPITAL REPORT.

THE TREATMENT OF TYPHOID FEVER AT THE PRESBYTERIAN HOSPITAL, NEW YORK.

COMPILED BY J. P. THORNLEY, M.D.,
OF NEW YORK;
ASSISTANT ATTENDING PHYSICIAN AND REGISTRAR TO THE HOSPITAL.

IN a systematic description of the treatment of typhoid fever, it seems but proper to mention what is known as the abortive treatment of the disease. At the Presbyterian Hospital this has met with but little favor. Patients with true typhoid fever who enter the hospital during the first week of the disease, form a small proportion of the cases admitted. On the other hand, a considerable number of patients, presenting the symptoms of an early stage of the disease, promptly recover after a few days of rest in bed and the administration of a mild cathartic. If these last are cases of typhoid fever, we do not *know* them to be such. The fact that they recover in so short a time, practically without treatment, must cast a grave doubt upon the efficacy of any form of so-called abortive treatment instituted before a certain diagnosis can be established. The introduction of the Widal method of diagnosis may help to clear up this point. Injections of antitoxin, prepared from cultures of the typhoid bacillus, have been used. They apparently caused the disappearance of all symptoms within one or two days, in a case of undoubted typhoid admitted during the second week of the disease. Several other cases were so treated with unsatisfactory results; therefore no conclusions could be drawn. As the Woodbridge treatment has not been carried out in the systematic manner recommended by its author, little evidence can be obtained for or against it in the records of cases in this hospital.

It will at once be seen, from the above remarks, that the plan of treatment practised is of the expectant and sustaining kind. The Brand method of tub-bathing, since its establishment here by Dr. W. Gilman Thompson in 1890, has gradually become the principal and most reliable means of carrying this out. As a majority of the cases are admitted during the second week of the disease, I will first briefly describe the management of such a case throughout. On admission, the patient's clothing is removed, he is immediately put to bed, given a tepid sponge-bath, and made as comfortable as possible. He is then seen by the house physician, who makes a physical examination, prescribes a milk diet, and, as the case may require, a mild cathartic, or some intestinal astringent. Unless there are other marked indications, this is all that is done at this time; it is a routine treatment followed in all cases. Should the patient give a typhoid history, however, and, on examination, an enlarged spleen and typical spots be found, tub-baths are ordered without further delay, and precautions taken against communication of the disease to others. Otherwise, he is watched until he has been seen by the attending physician. He is visited by some member of the house staff at least three times a day, and oftener if necessary. Once a day he is seen by the attending physician, and once in the twenty-four hours a careful examination is made of the condition of the mouth and tongue, abdomen, heart-sounds, pulse, and posterior chest. During the whole course of his illness, and for ten days after his first subnormal temperature, he is kept flat on his back in bed. His diet is entirely a fluid one. The bowels are regulated according to the necessities of the case, and the temperature controlled by means of baths, according to the rules given below. This treatment, in mild, uncomplicated cases, is frequently all that is required. A number of patients make good recoveries with this alone, and the constant care and attention of the nurses; but, on the contrary, the greater number require more radical measures. I shall take up, seriatim, the various symptoms presented, and describe the methods by which they are met.

NERVOUS SYSTEM.

Headache is a fairly constant and usually very distressing symptom of the early stages of the disease, and it is at the same time one of the most difficult to control, it being due in so many instances to the toxemia. When due to constipation or decomposition of intestinal contents, the following treatment is made use of: Calomel in one-tenth grain doses is administered every hour until ten doses have been taken, and this is followed by half an ounce of sulphate of magnesia, if necessary. At the same time, salol and phenacetin, each 5 grains, may be administered every four hours for a few doses. When the pain is caused or greatly aggravated by the increased force and frequency of the heart action, tincture of aconite, 1 minim every hour, for eight or ten doses, may be administered in place of the salol and phenacetin. The effect of either of these forms of treatment should be anticipated by the application of an ice-cap or cloths wrung out in ice water to the head, or of a small mustard plaster to the nape of the neck. Should the abnormal temperature be the cause of the headache, the latter will be relieved by the institution of the baths. Often enough all measures fail, and the headache finally passes off of itself. Rare forms of headache due to cerebral complications, coming on later in the disease, and that of convalescence due to the anemia, are dealt with by treating the cause.

Sleeplessness.—During the first ten days when the patient is kept awake by the headache or by pure nervousness, 15 grains of trional and $\frac{1}{4}$ of a grain of codein usually procures sleep. Such sleep is of genuine benefit and comfort to the patient, and there is no hesitation in so procuring it. When the sleeplessness is due to the pain of complications, morphin is administered, hypodermically, in sufficient doses to give relief.

Delirium.—Since the introduction of tub-bathing, delirium severe enough to require special treatment, is rare. Occasionally a patient becomes wildly delirious, rendering it necessary to have an attendant by him at all times. A previous alcoholic habit aggravates and predisposes to delirium in typhoid as in pneumonia. Leaving out the presence of excessive toxemia and cerebral complications, it is usually due to three causes acting separately or together, *viz.*, high temperature, asthenia, or over-stimulation. For the delirium of high temperature the baths usually suffice, while for that of asthenia it is necessary to push the stimulation until the circulation is improved. A very frequent cause of a wild and restless form of delirium is the administration of excessive quantities of whisky. This should always be remembered when even moderate doses are given, and the quantity should be reduced and the other stimulants be increased if necessary. It is imperative that the wildly delirious and maniacal patients should be constantly watched, for they are certain to get out of bed if left alone, and it then becomes a matter of chance whether they do themselves serious harm or not. Fortunately, only a very few resist all forms of treatment, and go from bad to worse, wearing themselves out by their constant movements. To these may be given $\frac{1}{100}$ of a grain of hyoscin and 3 to 5 minims of Magendie's solution. This cannot be repeated very often with safety, and it is only temporary treatment at best. One should hesitate to give it except as a choice between two evils.

TREATMENT OF TEMPERATURE.

Bathing is our most reliable means for reducing temperature. Not only do the baths reduce the temperature, but they powerfully stimulate the circulation and respiration. This will be evident to any one who studies the temperature chart of a typhoid patient who has been so bathed; while the sense of increased comfort and improved general condition of the patient is forced upon the attention of the unbiased observer at the bedside. Statistics of other hospitals the world over abundantly show the efficacy of this form of treatment when begun early in the course of the disease. The following facts, which bring this out very clearly, are offered as a contribution to what has already been written on the subject. They have been obtained from an analysis of 200 cases admitted from January 17, 1893, to December 31, 1895, and are not selected in any sense of the word. The full tables will be published in the Presbyterian Hospital Report for this year:

TABLE NO. 1—ANALYSIS BY WEEKS.

	First Week, Per cent.	Second Week, Per cent.	Third Week, Per cent.	Fourth Week, Per cent.
Mortality	7.8	7.4	18.	42.9
Complications and relapses	23.6	45.5	45.9	50.
Average duration, weeks	5.1	5.8	7	7.4

Patients admitted during the first two weeks of the disease, exclusive of five patients moribund on admission, show a mortality of between 7 and 8 per cent., and an average duration of about five weeks. It may be said of these patients that they had the full benefit of hospital care, as well as the advantage of the baths. On the other hand, those admitted during the third and fourth weeks of the disease show a mortality of 18 and 42 per cent., respectively, and an average duration of about seven weeks.

A further analysis of patients admitted during the first and second weeks gives the following table:

TABLE NO. 2—PATIENTS ADMITTED DURING THE FIRST TWO WEEKS OF THE DISEASE.

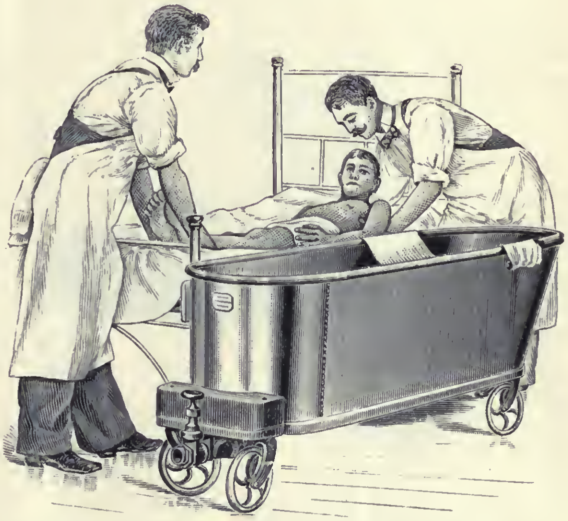
	Tub Bathed.	Sponge Bathed.	Tub and Sponge Bathed.	No Baths.
Number of patients	47	25	58	14
Percentage of mortality	4.1	11.5	13.7	..
Average time in hospital (weeks)	5.7	6.1	6.8	4.5
Average duration (weeks)[1]	5.6	5.5	5.8	4.2
Percentage of complications and relapses	37.5	34.6	55.1	17.6

This table is striking, in that it shows a high mortality among the patients treated by sponge baths alone. These cases would seem to have been of about the same grade of severity as those tubbed, if the average percentage of complications and duration is any index. Taking the same data as an index of severity, those treated by both tub and sponge baths were of a severe and prolonged type. Again, those patients who received no baths were suffering from a mild attack, and their temperature did not reach the bathing point often enough to make baths necessary.

So much for the results of tub bathing as carried out in this hospital. The mode of procedure is as follows:

A long narrow tub filled with water at a temperature of 75° F. is rolled close to the side of the bed. The screens are drawn about both bed and tub. The patient's ears are now plugged with cotton, and a binder placed about the loins. Two attendants firmly grasp the shoulders and feet and lift him from the bed into the tub. While in the bath his head rests upon a rubber cushion, the rest of his body being entirely submerged. His whole body, except the abdomen, is now vigorously but gently rubbed, special attention being given to the back. At the same time his head and face are kept constantly soaked with ice water. At the end of fifteen minutes of this treatment he is removed from the tub. The bed has been freshly made in the meantime and covered with two rubber blankets, and these, in turn, by an ordinary sheet. With this sheet his body is immediately dried. The rubber blankets are now removed and the patient finds himself in a dry, clean bed. He is now covered with a sheet and blanket, given a drink of hot milk or hot whisky and water, and a hot water bottle is placed at his feet. After an hour the blanket is removed, leaving only the sheet as a covering, and his temperature, pulse, and respiration are taken and recorded. Unless suffering from an actual chill, patients with fever are covered only with a sheet, and when receiving baths, as a rule, no night clothes are worn. They soon get used to this, although at first they seem to miss the comforts of home in the shape of two or three suits of flannel underclothing, all worn at once to "prevent taking cold."

Fig. 1.



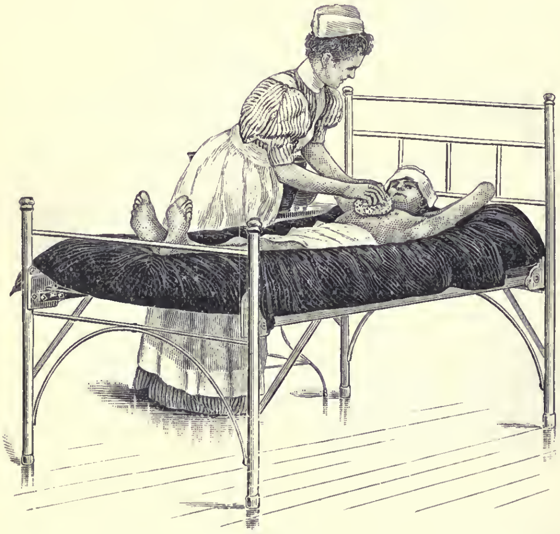
Method of administering a tub-bath to a typhoid fever patient.

This is the routine followed in each case of tub-bathing. The temperature of the patient is taken, per rectum, every four hours, as well as one hour after each bath. When the temperature at the fourth hourly observation reaches 102.5° F. he is given a bath as above described. The question of how the baths are borne is an important one and varies with the standpoint from which it is viewed. In a large number of instances the patients regard it as a distinct hardship and often bitterly complain of it. On the other hand, the cases are not rare in which the baths are enjoyed and are looked forward to with pleasure. The ultimate result is the same in both these cases provided the patient belonging to the former class does not put his objections into the form of actual resistance. Too much stress cannot be laid upon proper and efficient rubbing, especially of the back. This region, hard to get at, is frequently neglected until the patient insists upon the attention. Rubbing not only adds greatly to the patient's comfort, but is the secret of success in tub-bathing. From the standpoint of the physician the majority of the patients bear the baths extremely well. It is the exception when one has to be removed from the tub before the time has expired. Shivering is a constant accompaniment of the bath and must be disregarded. The pulse becomes small and wiry soon after the patient is placed in the water, thus demonstrating the stimulation to the circulation. Toward the *end* one expects to see slight cyanosis, which is of little importance. Syncope or marked cyanosis are indications for immediate removal from the bath. The patients excepted from this treatment are few. Patients suffering from collapse, hemorrhage, perforation, peritonitis, pleurisy, or pericarditis, or those who are weak and debilitated from other causes, usually women and old people, and occasionally one who strenuously objects, are not given tub-baths.

---

[1] Duration computed to tenth day after first subnormal temperature is therefore much longer than is ordinarily stated.

FIG 2.



Method of administering a sponge-bath to typhoid fever patient.

The sponge bath is given for high temperature when from any reason the tub baths are not practicable or advisable. It is given as follows: Two stout rubber sheets are placed under the patient and two rolled blankets under these, one on each side, forming a kind of trough. His ears are plugged with cotton, and a binder placed about the loins, as in the tub bath. He is now sponged from head to foot with water varying in temperature from 90° to 60° F. From time to time the water is squeezed from the sponge at a distance of one or two feet above the chest. This is kept up for fifteen minutes, as in the tub bath, and the after-treatment is the same. The advantages of the sponge-bath are, the facility with which it is given, no tub being necessary, and the fact that the patient is not moved from the bed. The disadvantages are, the lack of stimulation to the pulse and respiration, and the fact that friction to the surface cannot be so effectually employed. The fall of temperature after a sponge-bath may be great, but in the majority of cases this is not so reliable as after the tub. A comparative study of the temperature charts of tubbed and sponged cases brings out the fact that pulse, temperature, and respiration remain stationary or go up more frequently after a sponge-bath than after a tub. Another point worthy of mention holds good of both tubs and sponges. Patients who complain bitterly of the length of the bath often seem to do better if the temperature of the water is lowered even to 60 or 65° F., and the time shortened to ten minutes. The wet pack or the ice pack are seldom resorted to here in the treatment of typhoid fever.

CIRCULATORY SYMPTOMS.

When the pulse is of good quality, not over one hundred to the minute, and the first sound of the heart is clear and distinct, stimulants are not given. In the majority of the cases, however, some time during the second week, or earlier, signs of heart weakness make their appearance. This is noted, first in the increase in the frequency of the pulse, second, in inequalities in the heart and pulse rate, and third, in weakening of the first sound of the heart. Whisky in half-ounce doses every four hours is the first stimulant used, and is given at the first signs of heart-failure. Should this not be sufficient, strychnin, one-thirtieth of a grain every four hours, or fluid extract of digatalis, three minims every four hours, are administered, either separately or together. At times all these are given together with good results. They are not without disadvantages, especially when given in excessive doses. Increase in the delirium, rapid heart, or vomiting, are not infrequent results of too large or too frequent doses of whisky. The amount and frequency should be reduced, under these circumstances, or it should be suspended altogether. When the stomach alone is affected, champagne with cracked ice is the best substitute.

Diarrhea or intestinal hemorrhage are indications for withdrawal of the strychnin. The former may be directly due to the drug, while the latter is aggravated by it, except in cases of intestinal hemorrhage due to passive congestion of the viscera. When strychnin is given in large doses, the reflexes should be examined each day and the quantity of urine excreted carefully watched. If this is not done and warnings heeded, a sudden reduction in the amount of urine excreted may be promptly followed by more or less alarming convulsions. Digatalis often disagrees with the stomach and may have to be withdrawn temporarily, or even permanently.

RESPIRATORY SYSTEM.

The bronchitis which accompanies typhoid fever receives no special attention. It usually clears up as soon as the tub baths are begun. Bronchopneumonia is not very common. It is prevented in a large measure by the effect of the tub baths, by careful cleansing of the mouth, and care during feeding.

When bronchopneumonia is established counter-irritation is resorted to and tub baths are persisted in. The baths seem to be of the greatest importance here. Passive congestion is guarded against by constantly changing the position of the patient. When the congestion is marked in degree it is an indication for increasing the stimulation. The occurrence of lobar pneumonia renders the suspension of the tub baths and the substitution of sponging necessary. It is treated on general principles.

DIGESTIVE SYSTEM.

Care of the Mouth.—Special attention is given to the cleansing of the mouth. A foul mouth with sordes on the teeth is not only a menace to the patient, but is looked upon as a disgrace by the nurse in charge. It is only seen in recently admitted cases. For cleansing purposes two solutions are used, *viz.*, lemon juice with a little glycerin, or a mixture of peroxid of hydrogen, one part, with lime water, three parts. Swabs are made by wrapping bits of soft cotton around the end of an ordinary wooden toothpick. With these swabs and one of the above mentioned solutions the teeth and gums are carefully cleansed, and the tongue gently scraped after each feeding, and oftener if necessary. Should the patient be annoyed by unpleasant tastes in the mouth, due to decomposition of food in crevices that cannot be reached, rinsing the mouth with the peroxid and lime water at occasional intervals will give great relief.

Eating Utensils.—Dishes, glasses, cups, spoons, and trays, are all kept separate from those in general use in the ward. After having been used they are scalded and then cleansed.

Diet.—Careful attention to the diet is of the greatest importance in the treatment of typhoid fever. Milk and alcohol in some form are the most reliable and satisfactory forms of food. Other articles of food than milk are used in certain cases, and at certain periods of the disease, as we shall see later. Alcohol, as a rule, is not used until it is also needed as a stimulant. From the day of admission until ten days after the first subnormal temperature, the diet is invariably a fluid one. The amount given is from 60 to 72 ounces during twenty-four hours (five or six ounces every two hours), the patient being awakened if necessary.

The disgust that some of the patients develop for milk is not to be wondered at, given as it is every two hours with the regularity of clock-work. Much can be done to relieve the monotony of such a diet and to prevent the lasting distaste which may develop for a most wholesome article of food. The following dietary was originated to meet just such a contingency, and for sake of brevity has been somewhat facetiously called "typhoid delicacies." It can be made use of at the height of the disease. One or the other of the articles mentioned are given in five or six ounce doses every two hours, and the ménu is varied according to the taste of the patient or the wishes of the physician: (1) Milk, plain or peptonized, with vichy or lime water; (2) junket (made with essence of pepsin); (3) beef tea; (4) mutton broth (strained, and free from fat); (5) arrowroot (made with milk or water, and flavored with vanilla or sherry); (6) egg albumen (made from white of egg shaken up with cold water, and flavored with lemon juice or vanilla). Ice-cream is also allowed in moderation, more as a delicacy than as a food. Three days after the first subnormal temperature he may be given a little milk toast. The following day, improvement continuing, he may have an egg poached in milk, or soft boiled, and a little tea. The next day his dietary may be still further varied by the soft part of half a dozen raw oysters, flavored with pepper or salt to the taste. On the tenth day he is given a chop or scraped beef sandwich. During the remainder of convalescence he is fed up as much as possible on a nitrogenous diet. When he leaves the hospital he is cautioned against indiscriminate eating of indigestible vegetables and fruits for a year.

Vomiting is prevented, mainly, by adherence to the strict rules of diet. One cannot help remarking the frequency with which patients are admitted with a history of persistent vomiting, which promptly subsides without any other treatment. The articles of food brought to many patients by their friends and confiscated by the nurses furnish ample proof of this. When vomiting does occur a cause is always sought for, and frequently found. When not due to complications such as peritonitis, perforation, etc., it is often caused by errors in diet or medication. The quantity of food is at once reduced, and lime water may be added to the milk, or it may be peptonized. Finally, the milk may be temporarily suspended altogether, and some other article of food, such as beef tea, substituted for it. Over-medication is frequently a cause of vomiting. A temporary complete suspension of all medicines by the mouth will often be all that is necessary to stop it. In these cases stimulants are given by hypodermic injection, or per rectum. For the vomiting of peritonitis and perforation morphin is given in large doses.

Irritability of the stomach, with or without assignable cause, may be allayed by cracked ice alone or with small doses of champagne. In the same way, 2½ grains each of oxalate of cerium and bicarbonate of soda, given every two hours, sprinkled on cracked ice or added to the milk, often gives prompt relief.

Diarrhea.—When the number of stools does not exceed two or three small liquid ones a day, they may be disregarded. When more frequent than this, some cause is looked for. When the stools contain undigested milk, the quantity is reduced or it is peptonized. Strychnin aggravates, or in large doses often causes, diarrhea. Suspension or reduction of the dose is of course indicated here.

Powders of subnitrate of bismuth, 30 grains, and powdered opium, 1 grain, every four hours, will usually control the most obstinate cases.

Constipation is a more troublesome feature. A routine measure is to order a soap-suds enema every other day if the bowels have not moved in the meantime. This, as a rule, is satisfactory. After the establishment of convalescence the patient is given every morning, if necessary, 5 or 6 ounces of Hunyadi water.

Tympanitis.—Efforts to prevent the excessive formation and retention of gases in the intestines have been made with varying success. Probably the most satisfactory results have been obtained from the use of salol in 5-grain doses every four hours as a routine measure. No ill effects have been noticed at any time. On the other hand, the occurrence of severe and intractable tympanitis seems to be rare when salol can be given early and its use persisted in. With marked distension of the intestines there may be serious interference with respiration and heart action, as well as much greater liability to hemorrhage or perforation. Here salol in one or two doses is worse than useless; its administration is simply a waste of time. The most prompt results follow the use of turpentine stupes prepared in the following way: The abdomen is first covered with a coating of olive oil. To a quart of water a teaspoonful of oil of turpentine is added, and the whole kept near the boiling point at the patient's bedside. Pieces of flannel, large enough to cover the entire abdomen, are soaked in this, wrung as dry as possible, and laid on as hot as can be comfortably borne. The flannel is at once covered by oiled muslin and both left in place for fifteen minutes, when the stupe should be renewed. It may be necessary to continue this for days, as the effects, though prompt, may be very evanescent. Great care should be taken not to excoriate or blister the skin. With the occurrence of marked redness the stupes should be discontinued for an hour or so, and then resumed if necessary. Should these measures fail, a soft rectal tube may be passed ten or fifteen inches into the bowel.

Intestinal hemorrhage unfortunately is not a rare complication. Every effort is made to guard against it by restricting the diet to fluids, relieving and preventing tympanitis, and treating congestion of the lungs and a failing heart promptly. Patients with chronic heart lesions or cirrhotic livers are liable to the severest and most fatal hemorrhages in spite of the greatest care. The treatment varies with the severity of the hemorrhage and the cause. In all cases the tub-baths are suspended until there has been a movement from the bowels free from blood. The milk should be reduced in quantity, and if undigested particles of food are being passed per rectum, it should be suspended altogether or altered by the addition of lime-water or by peptonization. Beef tea may be substituted, and water given in almost unlimited quantities by the mouth. The routine treatment, in addition to the above, is to give the patient at once a hypodermic injection of 5 minims of Magendie's solution of morphin. This is repeated every four hours, in 3 minim doses, if the respirations are above fifteen to the minute, the effort being to maintain absolute quiet by means of as much opium as the patient can stand. Should there be a tendency to congestion of the lungs, $\frac{1}{100}$ of a grain of sulphate of atropin must be added to the morphin. The respirations cease then to be an index as to the amount of morphin necessary, and the physician must depend upon his own judgment. The application of cold to the abdomen in these cases has been abandoned as useless. The effort should be to prevent the occurrence of reflex peristalsis by sudden chilling of the abdomen, and this is attempted by having the patient wear a pad night and day. Should the temperature rise to 103° F. or more, and continue there for any length of time, the patient is given sponge-baths at a temperature of from 85° to 95° F. Subnitrate of bismuth in 30-grain doses is given for any diarrhea present, but the greatest reliance is placed on the opium to check the hemorrhage.

In the milder and even moderately severe hemorrhages this is all that is necessary. In those cases of grave severity, and even in the milder ones before their extent is known, the foot of the bed is elevated, pillows are removed, hot water bottles are placed in the bed, and the patient is covered with blankets. Stimulants are cautiously used, and intravenous injections may be given. As a rule, however, the more quiet the patient is kept and the less he is disturbed by efforts to relieve him, the better the chance of recovery.[1]

The Stools.—Under the head of "typhoid precautions" is included the care of the stools. Separate labeled bedpans are used for patients suffering from typhoid fever. After each dejection a pan is thoroughly cleansed and a few ounces of a 1 to 1000 solution of bichlorid of mercury is allowed to remain in it. The dejections are received into this solution, and as soon as the pan is taken to the lavatory the feces are covered with a 1 to 20 solution of carbolic acid and allowed to stand, well covered, for an hour or two before being disposed of.

The bedding and clothing of the patient, when removed from time to time, are at once sprinkled with a 1 to 20 solution of carbolic acid. They are then placed in a tub containing carbolic acid solution of the same strength, and remain their over night. They are then sent to the laundry. During five years not a single case of typhoid fever has developed among the employes in the laundry. On the other hand, hardly a year passes that a physician, nurse, or orderly, does not contract the disease. Everyone is cautioned about washing and disinfecting the hands after coming in contact with typhoid fever patients, but that some are careless is shown by the above statement.

URINARY SYMPTOMS.

With the large ingestion of fluids, severe kidney complications are rare. Most of the patients have a slight albuminuria at some time during the progress of the disease. A number also have a few hyalin or epithelial casts. As long as the daily amount of urine does not fall below twenty-five or thirty ounces, the albumin does not exceed one per cent., and the casts are largely hyalin, nothing more is done than to see that the patient receives a large quantity of fluids. More severe complications are treated on general principles. The baths are not discontinued for the milder forms of renal disturbance, but acute congestion renders their temporary suspension necessary.

---

[1] Perforation and peritonitis become at once a surgical complication, and the advice of a surgeon should be promptly obtained. Medically, morphin in large doses, and absolute quiet, as in hemorrhage, give the only hope of recovery.

SKIN SURFACE.

Furunculosis and Bed Sores.—Undoubtedly furunculosis is more frequent among patients who systematically receive tub baths. This is due in a large measure to the constant friction necessary during the baths. With care and gentleness their occurrence can be reduced to a minimum but not altogether prevented, patients with a delicate skin being especially subject to them. The boils are troublesome and painful but seldom if ever reach serious proportions. They are first treated with compresses soaked in a one to eighty solution of carbolic acid, the dressing being held in place by means of rubber adhesive plaster. When suppuration occurs, the boils are incised, curetted if necessary, irrigated with a 1–1000 solution of bichlorid of mercury and packed with iodoform gauze, the dressing being held in place by adhesive strips. The baths are continued, the dressing being removed after each one. Cellulitis is a more serious complication and must be dealt with according to surgical principles.

Bed sores are very rare even in the most protracted cases. They are almost entirely preventable, and the average nurse looks upon their occurrence in a patient under her care as a disgrace. They are prevented, first, by the manner of making the bed and keeping the clothing smooth, and by frequently changing the patient's position; secondly, by removing all bedding and clothing that is the least moist or soiled; thirdly, by frequently bathing the areas most subject to pressure with a solution of fifteen grains of alum in one ounce of alcohol, drying the skin thus bathed, and dusting talcum powder on the surface. On the appearance of the slightest redness the patient is frequently moved from side to side and propped in this position by means of pillows. When a bed sore does develop it is kept clean and efforts to relieve pressure are redoubled. It may become necessary to resort to the use of the water bed.

Phlebitis and periphlebitis are very frequent complications and may occur during the disease, after convalescence is established, or later. By preference they most often occur in the internal saphenous vein. Of the rarer forms it is not within the scope of this article to treat. The affected limb should be kept as quiet as possible. If the patient is already up and about he should be sent back to bed. For the first few days the limb should be elevated on pillows and enclosed in cotton from the toes upward. If there is much pain, relief may be obtained by the use of compresses wrung out in a hot solution of lead and opium and applied in place of the cotton until the pain has subsided. As soon as the acute symptoms have passed off, the swelling and edema are reduced by means of a canton flannel bandage snugly applied. With this in place the patient may move about after a week or ten days, should it be proper otherwise for him to do so. When he leaves the hospital he is advised to wear an elastic stocking and to favor the leg as much as possible.

Peripheral neuritis is not common and is treated on general principles. The rarer complications will only be mentioned. Perichondritis is treated by cold; later, surgically, if necessary. Abscess of the thyroid gland becomes a surgical affection and is treated accordingly, also ischiorectal abscess, which should be opened promptly, the patient being anesthetized even at the height of the disease in order that it may be thoroughly done.

Lately, attention has been directed to what has been called, for want of a better name, "tender toes." This painful affection develops toward the end of the disease in a moderate number of cases. It is characterized by tenderness and hyperesthesia of the toes, which, to judge from the facial expression of the patients even before they are touched, must be very severe. The pathology is in doubt, and the hyperesthesia is the only sign of neuritis. The bed clothes must be raised from the feet by means of a cradle and the pain relieved by applying a mixture of menthol and spirits of camphor (grs. xv—℥ i).

MANAGEMENT OF CONVALESCENCE.

On the third or fourth day after the first subnormal temperature, the patient sits up in bed for a short time. The improvement continuing, he sits up a little longer each succeeding day. On the tenth day he is lifted in a blanket to a chair, and may sit there for an hour. The pulse-rate is taken before he leaves the bed, five or ten minutes after sitting in the chair, and just before he goes back to bed. This gives a good idea of the way in which his heart responds to the extra work thrown upon it. At the same time it is a valuable guide to the length of time he can remain up the next day. In two or three days he is given his clothes, and can walk about as he feels able.

It seems well to here speak of those patients, undoubtedly convalescents, who have an afternoon temperature of from 100° to 101° F. without assignable cause. A more liberal diet and light exercise, in these cases, will bring the temperature to normal. It would seem as though this rise of temperature was due to a mild form of starvation or anemia. These patients often cause no end of anxiety. No fixed rules can be given for their identification, the physician being compelled to depend upon his own judgment. It is undoubtedly best to be on the safe side and move with caution, for fear of relapse. Recrudescence and relapse simply require a resumption of treatment, as given above.

In conclusion, I wish to express my thanks to the members of the medical board of the Presbyterian Hospital for the courtesy shown me in the preparation of this paper.

MEDICAL PROGRESS.

Rare Pancreatic Tumors.—Sendler had the good fortune to operate successfully upon a tumor of the pancreas. The patient was a woman, aged fifty-four years, in whom, after nine months of slight digestive disturbance and emaciation, a rough, movable tumor could be made out in the navel, in the middle line. Examination of the contents of the stomach was negative. There was no pyloric obstruction and no intestinal symptoms. On account of the age of the patient and the loss of flesh and strength, a diagnosis of a malignant growth was made, either of the posterior wall of the stomach, or of the pancreas. At operation the liver, gall-bladder, and intestine were found to be healthy. The stomach was situated low down, so that the hard, rough tumor of the pancreas was most easily approached above the lesser curvature. After division of the lesser omentum longitudinally, the head of the pancreas was brought forward, and a grayish-yellow tumor about the size of a walnut was resected. The bleeding was profuse, but was readily controlled. The pancreatico-duodenal lymph glands were enlarged, and were removed. Other enlarged glands near the spinal column were not disturbed. The abdomen was closed without drainage. Recovery from the operation was prompt. Thorough microscopic examination of the tumor showed it to be tuberculosis of lymph glands lying in the pancreas. The other lymph glands, which were removed, were also tuberculous. As the patient gave no evidence of tuberculosis elsewhere in the body, Sendler looked upon this case as one of primary pancreatic tuberculosis. It possesses an additional interest, in that lymph glands in the pancreas have not heretofore been recognized.

Another patient, also a woman, who had suffered for years with epigastric pain, vomiting, and loss of appetite and flesh, presented in the region of the stomach, extending toward the left from the median line, a rounded, tender tumor, which, under narcosis, was somewhat movable. Under the impression that a carcinoma of the stomach existed, laparotomy was performed. After division of the lesser omentum it was seen that the whole pancreas was swollen, of a gray color, and very hard. The head especially was nodular. The other abdominal organs appeared healthy. The tumor was considered an inoperable carcinoma, and the abdomen was closed. There was a good recovery from the operation, but the condition of the patient grew worse until death was expected. Then, without known cause, the symptoms gradually disappeared until, at the end of a year, she was again in good health. Three and a half years later, a greatly diminished tumor could be felt in the original situation. This case demonstrates the existence of a benign chronic inflammation of the pancreas which may be recovered from.

Biondi, who has also made a study of this subject, considers that the surgery of the pancreas has remained undeveloped on account of (1) the difficulty of diagnosis due to the similarity of symptoms arising from disease of the pancreas and of neighboring organs; (2) the difficulty of operating upon the pancreas on account of its tendency to bleed and its friability. Total extirpation of the pancreas is absolutely fatal. Most of the operations performed upon it have been for cysts. He himself had removed a fibro-adenoma of its head with success.

By a series of experiments upon dogs he had determined: (*a*) If the duct is not disturbed a portion of the head of the pancreas may be removed. (*b*) If the whole head is removed it is impossible to bring the pancreatic juice into the intestine, and death therefore follows. (*c*) Pancreatic juice can indirectly cause peritonitis, and its escape into the peritoneal cavity is therefore to be avoided. (*d*) No animal, the whole of whose pancreas had been removed, lived more than twenty-three days. Biondi considers that surgical interference is indicated in cysts, hemorrhages, suppurations, localized areas of fat necrosis, primary tuberculosis, calculi, and benign tumors of the head. An exploratory laparotomy is often necessary to establish the diagnosis. (*Deut. Zeitschr. f. Chir.*, vol. 44, p. 329, *Centralbl. f. Chir.*, No. 59, 1896.)

Accident Following an Injection of Iodin Into a Hydrocele.—CHAVOIX (*Gaz. Médicale*, Jan. 16) mentions an instance in which a hydrocele was tapped and injected with 200 grammes of a fluid containing iodin. Eight days later the patient was taken with violent chills, and petechiæ appeared all over his body. Later there was epistaxis and hematuria, followed by hiccup and fever.

THERAPEUTIC NOTES.

Sage as an Antisudorific.—KRAHME (*La Médicine Moderne*, Jan. 13) calls attention to the fact that the tincture of sage, given in doses of twenty drops in the morning and forty in the evening, has given him excellent results in the treatment of the annoying night-sweats which often accompany pulmonary troubles. In thirty-eight cases it failed only twice to give relief. The effect was obtained only during the administration of the medicine, and as soon as it was withheld the sweats returned. No ill effects were observed from its use. Instead of the tincture, an infusion may be made by using one teaspoonful of the dried leaves to a pint of water.

Internal Esophagotomy.—WEBER (*Centralblatt f. Chirurgie*, No. 3, 1897) has collected all the known cases of internal esophagotomy since 1861. There are are twenty-five of these. As regards instruments, those which cut the stricture from above downward are bad, as it is impossible to tell how far the instrument will cut. The incision should be made from below upward. The best instrument is one devised by Schiltz, in which the blade is protected and passed through the stricture. It is then projected to a known distance, and is drawn upward, cutting its way through the stricture. Several shallow cuts are better than a single deep one. One can cut to a depth of two millimeters without danger.

The operation has usually been performed for strictures resulting from the swallowing of some caustic material. It has three times been performed for carcinoma of the esophagus, and without bad effect. It is especially indicated in strictures which are too low down to be reached from the neck, and which implicate only a portion of the esophageal wall.

Pellotin as a Hypnotic.—LONGSTEIN (*Centralblatt f. innere Med.*, No. 3, 1897) saw a deep collapse, which lasted half an hour, follow the subcutaneous injection of one-sixth of a grain of pellotin in a two-per-cent. solution.

THE MEDICAL NEWS.

A WEEKLY JOURNAL
OF MEDICAL SCIENCE.

COMMUNICATIONS are invited from all parts of the world. Original articles contributed *exclusively* to THE MEDICAL NEWS will after publication be liberally paid for (accounts being rendered quarterly), or 250 reprints will be furnished in place of other remuneration. When necessary to elucidate the text, illustrations will be engraved from drawings or photographs furnished by the author. Manuscripts should be typewritten.

THE TUBERCULOSIS QUESTION IN NEW YORK.

THE more thought and inquiry that is given to the practical application of the recent enactment of the Board of Health, the more the conviction grows that the ominous and threatening wrongs that have been conjured up are but creatures of a diseased fancy—nightmares of an unfounded suspicion. Self-glorification is not the motive, nor is there any inherent tendency to alarming bacteriological edicts, officiousness of inspection, or presumptuous instructions to patients. On the contrary, the wise and judicious manner in which the Board has been applying, for the past four or five years, the very regulations about which now so much effort is being made to stir up commotion, is an earnest of how they will be administered in the future.

Criticism has been offered because the Board has not enforced to the letter its rule regarding expectoration in the street cars, elevated stations, and other public places. In answer to this it may be said that there is no surer way to make a good law unpopular than to enforce it offensively. Enactments of Boards of Health are not for the purpose of affording display of arbitrary power. No law can be enforced very long in any community unless it has the moral support of the best element of that community. And least of all can regulations concerning hygiene and sanitation meet with success unless the public approves. The campaign, therefore, becomes one of education, backed up by a wise enforcement of law whenever it becomes necessary to teach the lesson in the more peremptory way. The placing of the regulations under discussion in the Sanitary Code was simply conferring the power to apply the whip in cases of persistent ignorance or obstinate rebellion.

The New York public has been learning the lesson, and is now ready to accept the conclusions; but opposition suddenly looms up from a most unexpected quarter—the medical profession. Hypothetical questions of might and right, aroused by fear of arbitrary power, and of injured rights could be argued *ad infinitum*. But to what good? No complaints are made now regarding the Board of Health regulations in the conduct of scarlet fever, diphtheria, measles, smallpox, etc. What reasonable ground is there to fear that useless display of power or officiousness of inspection will be practised in a similar control of tuberculosis? It is an innovation, to be sure, but it is in the line of progress, and the medical profession should welcome it as a proffered assistance in its efforts to combat the greatest enemy of mankind. The following editorial comments in the New York *Herald* of February 26th, coming as they do from the lay press, indicate the feeling of the general public on the subject: "In large cities physicians are required to give notice to the health authorities of cases of certain infectious diseases, the mortality of which is small compared with the mortality of consumption. There is every reason, therefore, why the New York Board of Health should be vigorously sustained in its endeavor to arrest the spread of tuberculosis."

THE NEED OF INSTRUCTION IN ETHICS IN OUR MEDICAL SCHOOLS.

AT the last meeting of the British Medical Association there was much discussion in the Section on Ethics concerning the local organization of the profession. When trying to explain the present-day want of *ésprit du corps* and lack of consideration among physicians in their conduct toward each other, Dr. Alexander Stewart struck the keynote of the whole subject when he said:

"I venture to think that the disappearance of the apprenticeship system has had much to do with the breaking down of the barriers which regulated the relations of neighboring practitioners—if they were ever there to break down. That system had at least this one advantage, that it accustomed the aspirants to the medical profession to the ethics and traditions of the profession before they became actually members of it. Whether it produced a higher type of practitioner than the system which has displaced it is a subject on which it would not become our modesty, who are the product of such system, to dogmatize. What more immediately concerns us now is that hundreds of young men are entering the profession every year—generous, high-minded, imbued with the enthusiasm of youth—crammed full of book knowledge, eager for opportunities of putting it into practice, but often ignorant of other things which would be good for them to know."

The apprenticeship system is irrevocably gone, it is true, and we give nothing in its place. In old student days, when we studied, talked, worked, walked, and drove with our preceptor, we were brought into closest contact with a living, struggling member of the profession we were about to enter. We knew his successes and failures, his joys and griefs, and perplexities. We heard him argue his problems logically, and deliver his opinions with judicial precision. Of course he made mistakes, but we learned more about real vital issues and human nature with him in one week than the student of to-day learns in four years.

On graduation at the present day, how much do students know of the actual conduct of practice; how much of that subtle personal equation so indispensable to success? Men graduate now with a better scientific and theoretical outfit than ever before, but a man may starve on such an equipment. Unless he knows how to conduct himself toward the public, his patients and his professional brethren, he will fail in spite of his acquirements. In the system of medical education now in vogue, this knowledge comes, if at all, only by experience, and hence but few attain material success, and fewer still professional distinction.

With our present large medical schools and classes, anything like personal acquaintance, to say nothing of intimacy, between professor and scholar is impossible. The influence of the teacher is scientific only; in no sense is it moral or paternal. In his teachers, the student sees the successful men and, with them as ideals, with never a word as to the trials, exactions, and hardships of professional life, he leaves the school and is launched on what he believes to be a roseate sea of applied science.

If luckily he gets a hospital appointment his awakening is deferred for a year or two; but it comes, and with it a smirching or shattering of ideals. Were the history of each class known we would find its track strewn with derelicts; men too poor in money, men too poor in brains, but, more than all, men scientifically well fitted for their work who, had their tutelage been more personal and confidential, would have turned back before it was too late or would have pushed on to moderate success through obstacles of which they were forewarned and for which they were equipped.

A reversion to the old apprenticeship system is impracticable, but something should be given in its place. To those students who cannot be dissuaded from entering an over-crowded profession, should be given, sometime during their course of study, a series of plain practical talks, by some member or members of the faculty, which will open their eyes to things which books and laboratories cannot teach, a course of future conduct which will tend to make them respected, self-respecting and, haply, materially successful physicians.

ECHOES AND NEWS.

The New York Hospital Training School.—At the annual reception and graduating exercises this year of the New York Hospital Training School for Nurses, twelve graduates received diplomas and badges.

Legal Objection to Vaccination.—The Supreme Court of Wisconsin has handed down the decision that a person who "deems vaccination morally wrong and in violation of the laws of God" is exempt from compulsory vaccination in that State.

A New Combustible.—The *Cincinnati Enquirer* gives an account of a new compound, the invention of John Floyd, which ignites by the slightest friction against any hard surface. No explosion occurs, but the substance burns with a steady, blue flame, and gives out intense heat until consumed. There is no known substance that will extinguish it.

Obituary.—Dr. John Kirby, one of the physicians in charge at the New Jersey Hospital for the Insane, near Trenton, died February 27th, aged seventy-one years. He had been connected with the hospital since 1876. Before coming to Trenton he practised medicine at Salem, N. J. Dr. Kirby was graduated from the University of Pennsylvania in 1848.

An Aged Medical Student.—The Maine Medical School at Portland, Me., boasts the oldest medical student in the country. He has just entered upon the three-years' course, and when he receives his degree of M.D., will have passed his sixtieth milestone. He is described as a gracious old-school gentleman with a kindly face. He is an ex-minister of the Baptist persuasion.

Marriage, Birth, and Death Certificates.—A bill is now before the New York legislature providing that a fee of twenty-five cents shall be paid by the municipality where a marriage, birth, or death has occurred, to the party making the proper certification of the occurrence. A like charge of twenty-five cents shall be made for every copy of such certificate furnished by the municipality to parties desiring them.

Serum Treatment of the Plague.—Professor Yersin has now in readiness a large number of immunized animals, and is about to apply, at Bombay, the serum treatment of the plague on a large scale. Experts from nearly all the civilized countries have gone to Bombay to scrutinize the effects of this treatment. If the experiment proves successful, it will be of inestimable value in establishing the great principle of serum-therapy.

Infectious Diseases in St. Louis.—The Board of Health and Health Commissioner of St. Louis have decided to double the number of depots at which physicians may obtain culture tubes, diphtheria antitoxin, etc. Circulars are now being prepared announcing eighteen new stations at which will be found culture tubes, diphtheria antitoxin, sputum bottles for suspected tuberculosis, and sterilized glass slides for collecting blood for typhoid fever tests.

A New Building for the Detroit College of Medicine.—The old home of the Detroit College of Medicine, which was unfortunately destroyed by fire some two months since, is to be rebuilt, on the former site, and considerably enlarged. The contract has been let, and the new edifice will be completed by the beginning of the autumn session. Temporary use is made of the adjacent laboratories and hospital for the remainder of the present term.

The Corset Habit.—At the Academy of Medecine of Paris the question of corsets has been to the fore. M. Laborde opened the discussion, and illustrated his remarks by X-ray photographs and the exhibition of a hygienic corset. M. Lucas Championnière, however, said that the corset in question was nothing but an abdominal belt, and condemned it on the ground that its constant use enfeebled the muscles of the abdominal wall.

Expert Testimony in Criminal Trials.—The New York *Times*, in commenting upon this subject, wisely says: "If public provision is made for expert testimony, it should be in behalf of the court, and for the purpose of getting independent and unbiased evidence for the enlightenment of both judge and jury, and not for the purpose of supporting one side of a case. Where it is necessary to establish scientific facts, hiring opposing experts to dispute over them is a tedious and costly as well as an unsatisfactory way of accomplishing it. What is needed is entirely competent and disinterested experts to tell the court and jury what the facts are, regardless of their effect upon one side or the other of the trial."

Editorial Comments on the Action of the New York Board of Health in Connection with Tuberculosis.—*Pediatrics* says: "We believe that the action of the Board of Health is timely to a degree, and in no way can we subscribe to the criticism that has come from certain quarters of the profession that we are not yet ready for such fin-de-siècle legislation. A judicious, temperate, and determined enforcement of the newly-framed rules will enhance the faith and trust that the citizens of this municipality have in its ability to guard their health and their lives. The action marks a step forward in the annals of civilization, and we believe that the example will be promptly followed by health boards of other cities.

Nansen on the Prevention of Scurvy.—Dr. Nansen is of the opinion that on his recent Arctic expedition he avoided all trouble from scurvy by simply preparing his provisions with the utmost care, being convinced that spoiled meat and fish were the cause of the malady. Dr. Torup, professor of physiology at the University of Christiania, had informed him that he had come to the conclusion that in the decomposition which occurs in meat that has been improperly or carelessly preserved, poisonous matter allied to the ptomains was developed, which, when partaken of, produced scurvy. Acting upon this suggestion, Nansen had paid particular attention to the selection of provisions in his equipment, and is inclined to subscribe to Torup's opinion.

Discovery of the Germ of Yellow Fever.—There seems to be no doubt of the fact that Giuseppe Ganarelli has discovered the bacillus of yellow fever. After studying with Celli at Rome, Roux at Paris, and Behring at Berlin, he was appointed in July, 1893, director of the Institute of Hygiene at Montevideo, Brazil. During the summer of 1896, for the purpose of studying yellow fever at the lazaretto, he went to the island of Flores, where he performed a large number of necropsies, and was himself stricken with the disease. Later, he pursued his investigations at Rio Janeiro, and succeeded in discovering the bacillus. He then occupied himself in the preparation of serum-antitoxin, and in these experiments inoculated over 2,000 animals. The results of his treatment are pronounced definitely convincing, but the details are for the present concealed for the reason that a prize of $150,000 offered by the Brazilian Government awaits the discoverer of a cure for yellow fever.

Abnormal Development of the Right Arm of a Child.—Dr. Goldstein, of the New York Polyclinic, recently presented at the clinic of Professor Fowler a child who has in her right arm two distinct humeri, each articulating with separate glenoid fossæ of the scapula; three ulnæ, two radii, and three perfectly formed hands. Each of the hands has four perfect fingers and each a perfect thumb. Not only this, but every muscle of every finger and thumb is under the control of the girl, and she can write and perform other operations with any hand. The girl is quite sensitive regarding her deformity. She is bright and studious, but dislikes attending school because she becomes so great a curiosity among her little classmates. Frank Martin, an expert medical photographer who is employed by the Polyclinic, has recently made some skiagrams of the arm, and these plainly show the existence of the distinct bones, humeri, ulnæ, and radii, and the manner in which the three hands are attached to the wrist.

Doctors' Bills Must Be Paid.—The New York legislature has under consideration a bill providing for the payment of debts, as follows: Every executor and administrator must proceed with diligence to pay the debts of the deceased according to the following order: (1) Debts entitled to a preference under the laws of the United States. (2) Taxes assessed on the property of the deceased previous to his death. (3) Debts of the deceased, because of services rendered and materials furnished by physicians, pharmacists, nurses, and undertakers. (4) Judgments docketed, and decrees entered against the deceased according to the priority thereof respectively. (5) All recognizances, bonds, sealed instruments, notes, bills, and unliquidated demands and accounts. Preference shall not be given in the payment of a debt over other debts of the same class, except those specified in the fourth class. All debts specified in the third class shall become due upon the death of the deceased and shall be paid within ninety days thereafter.

The New York University Medical School.—The long contemplated combination between the University of the City of New York and the University Medical School has been formally effected. The title to the Medical School property has been formally transferred to the Council of the University. This gives it absolute jurisdiction over the Medical School and completely amalgamates it as a department of the University. The University Medical School was established in 1841, and is one of the old medical institutions of the country. The property, situated in East Twenty-sixth street, is complete in every particular, and in the course are embraced eighteen departments. The value of the buildings is estimated at $300,000, which, with an endowment fund of $100,000, makes the value of the gift amount to $400,000. The medical school for many years has been practically under the jurisdiction of the University Council. It has been directly under the control of a board of trustees, but its action has been subject to the supervision of the council.

The Health Board of Greater New York.—In commenting on the provisions of the new charter with reference to the Health Board, Dr. Stephen Smith says: "It is especially provided that of the three commissioners appointed two shall be physicians and one a layman, and that the layman shall be president of the board. Under no consideration can a physician hold that office. Thus a lawyer, grocer, cobbler, pedler, or any tramp, just so he has no medical knowledge, is declared qualified for the position, and the only disqualification is being a physician. In defence of this the superannuated theory is set up that a physician has no executive or business ability; but experience has proved that this is a fallacy. The president of the National Board of Health is a physician, and the report submitted by him to Congress was declared a model of accuracy and conciseness." As a remedy for these evils, Dr. Smith suggests that the charter be so amended as to provide for the representation of the three essential requisites, namely, medical science, sanitary engineering, and law, in the Health Department, and to that end he advocates the appointment of three physicians, one lawyer, and one sanitary engineer, all of ripe experience and residents of the boroughs of Manhattan, Brooklyn, Bronx, and Queens as commissioners, with the health officer and the president of the Police Department as ex-officio members of the board, so as to provide a restricting power, the president of the board to be elected by the commissioners themselves.

Medical Aid Societies in Austria.—A meeting, which brought together about 1,000 medical men from all quarters of Vienna, was held on February 9 for the purpose of protesting against the Government proposal to make insurance against sickness obligatory on employers and tradesmen. Dr. Scholz quoted statistics, showing that, according to the conditions of medical practice, which either existed, or may be expected very soon, it is inevitable that only one medical man in six will be able to make a livelihood. He reminded his hearers that they were in duty bound to refrain from intensifying the hardships of the situation by unprofessional competition. He was of opinion that every medical man should be employed by the State, and that the profession should be efficiently organized. Dr. Horz said the Government proposal to establish medical aid societies among the middle classes, if carried out, will be the ruin of the medical profession; the needy practitioner suffering from the stress of competition and inadequate remuneration will be only too likely to disregard ethical considerations. The present system of treating club members is objectionable, for it leaves the patient no choice in the selection of his adviser. Moreover, no medical man can make two hundred diagnoses in a day and give the requisite attention to individual cases. As a result the following resolutions were unanimously adopted: (1) The system under which members of clubs and friendly societies combine to obtain medical attendance is opposed to the interests both of the patient and the medical officer; (2) the proposal to extend the principle of insurance against sickness and to render it compulsory on employers of labor and tradesmen will have a disastrous effect on the medical profession; and (3) the "free-choice" system under which patients have the option of selecting their medical attendants is preferable to the existing method.

State Board of Medical Examiners.—The law regulating the appointment of medical examiners is being modified by the New York Legislature as follows: There shall continue to be three separate State boards of medical examiners of seven members each, each of whom shall hold office for three years from August 1st of the year in which appointed. One board shall represent the Medical Society of the State of New York and the New York State Medical Association, one the Homœopathic Medical Society of the State of New York, and one the Eclectic Medical Society of the State of New York. Each of these four societies shall at each annual meeting nominate twice the number of examiners to be appointed in that year on the board representing it. The board representing the Medical Society of the State of New York and the New York State Medical Association shall be composed of members from each of such organizations, to be appointed as follows: At the annual session of the New York State Medical Association held during the year 1897, nominations shall be made for all vacancies occurring in such board, by expiration of term, during the year 1898; and thereafter the New York State Medical Association, and the Medical Society of the State of New York, shall each be entitled annually to the appointment of one member. In the years when three members of such board are to be appointed, the appointment of the extra member shall alternate between such two organizations; but when three members of such board are next to be appointed, the extra member shall be appointed from nominations made by the New York State Medical Association. All vacancies occurring, otherwise than by expiration of term, shall be filled by appointment from the organization to which the member belonged, whose office is vacated. The names of nominees for appointment to such State boards shall be annually transmitted under seal by the President and Secretary prior to May 1st to the regents, who shall, prior to August 1st, appoint from such lists the examiners required to fill any vacancies that will occur from expiration of term on August 1st.

CORRESPONDENCE.

A PRECOCIOUS MOTHER.

To the Editor of THE MEDICAL NEWS.

DEAR SIR: As an instance of precocity, I think the report of the following case may be of interest. On January 28, 1896, I attended in labor a young mother of twelve years and ten months of age. I ascertained that she had menstruated but twice prior to her marriage. She was fairly well developed for a child of her age, but fortunately for her labor came on at about the end of the seventh month. The babe was born breech first, and although living before labor set in, died during the expulsion. Yours truly,

WM. M. FINDLEY, M.D.

ALTOONA, PA.,
February 8, 1897.

CRETINS IN AMERICA.

To the Editor of THE MEDICAL NEWS.

DEAR SIR: Will you kindly allow me the use of your columns to ask for information on the subject of cretinism in America? I have been detailed by the Pediatric Society to take part in the discussion on *Internal Secretions* at the Congress of American Physicians and Surgeons at Washington, on May 5th, and I am anxious to present the experience of American physicians on the use of the thyroid extract in the treatment of cretinism. I wish brief statements, (1) of the name, age, and sex of the patients; (2) of the length of time the thyroid extract has been given, and with what results; (3) whether any case cured by treatment has been able subsequently to abandon the use of the extract; and I would also like to have photographs showing the effects of the treatment.

I shall of course give full credit to any of my colleagues for the information they may kindly furnish. I have the details of the cases already published in this country, but shall be glad of any additional data as to the subsequent history. Very truly yours,

WILLIAM OSLER.

1 W. FRANKLIN STREET,
BALTIMORE, MD., March 5, 1897.

OUR PHILADELPHIA LETTER.

[From our Special Correspondeut.]

MEETING OF THE NEUROLOGICAL SOCIETY—ARSENICAL NEURITIS IN CHOREA—PRIMARY NEUROTIC ATROPHY—HYSTERICAL PARALYSIS—SPASTIC DIPLEGIA—MEETING OF THE PHILADELPHIA COUNTY MEDICAL SOCIETY—THEORY OF THE MOVEMENT OF THE NEURON.

PHILADELPHIA, March 8, 1897.

AT a recent meeting of the Neurological Society Dr. Alfred Stengel presented a case of arsenical neuritis. The patient, a child aged five years, was under treatment for chorea, and had been taking Fowler's solution of arsenic in 10 minim doses three times a day. The improvement was so marked that he was discharged from the hospital. About one month later the child was brought back with symptoms that pointed towards the toxic influence of arsenic either on the peripheral nerves or the cord.

Two cases of primary neurotic atrophy, interesting from their rarity, were reported, one by Dr. Burr the other by Dr. Dercum.

Spastic diplegia occurring in four children of the same family was reported by Dr. F. X. Dercum. The father had been married three times. The children of the first and second wife were normal. By the third marriage there were four children, all epileptics, and three of them showed the symptoms of spastic diplegia. In each case the child at birth was perfectly normal, but within a year or so the conditions mentioned made their appearance without apparent cause, save in one instance when an attack of measles seemed to bear a causal relation.

An interesting case from the standpoint of diagnosis was shown by Dr. Spiller. The history of the patient, a man about thirty-five years of age, prior to the year 1891 is entirely irrelevant to his present condition. During the summer of that year at Atlantic City, N. J., he rescued two men from drowning after supreme effort and barely escaped losing his own life in the attempt. He was able to return to Philadelphia the same evening, however, and that night performed the usual routine of his occupation on one of the leading daily papers. On the morning of the next day upon attempting to rise from his bed he suddenly fell unconscious, but remained in that condition for a short time only. On returning to consciousness he found himself unable to move the entire right side of his body, and while cognizant of what occurred about him was unable to speak or call for assistance. He was able before the attack to converse in, and write fluently, Danish, Swedish, English, French, and German. When found he was removed to the hospital where examination revealed complete anesthesia of the affected side to the median line in addition to the loss of power already mentioned. His aphonia persisted, and he was unable even to understand any of the languages with which he was formerly conversant except his mother tongue, Danish. Speech, however, was gradually regained, at first in the Danish language, and afterward as if learning them all anew the other languages were recalled. The hemiplegia has greatly improved, *i.e.*, he is able to walk with a typical post-hemiplegic gait and power has been restored in great degree to the affected arm. On attempted motion of this member there was developed and is still present a marked coarse tremor. This has been of such gravity, and has assumed such proportions in the eyes of the patient that he has requested that the arm be amputated. In fact he attempted suicide by shooting because of his depression due to a refusal to comply with this request on the part of the attending physician. There never was any interference with genito-urinary function. In the discussion of the case Drs. Sinkler and Dercum confirmed the diagnosis given by Dr. Spiller, *i.e.*, traumatic hysteria.

At a recent meeting of the County Medical Society Dr. F. X. Dercum read an exceedingly interesting paper on "The Theory of the Movement of the Neuron as applied to Normal and Pathological Mental and Nervous Processes." After outlining the development and history of the neuronic theory he explained the application of it to such conditions as hysterical paralysis, sleep, perception, insanity, etc.

The paralysis of hysterical type is due to the severing of the connection between the cortical and spinal neuronic interdigitations which hypnotic suggestion might restore indirectly through auditory stimulation. Sleep is the decrease of neuronic volume through fatigue. Memory is the permutation or combination of neura first affected by external stimuli through the various perceptive channels and recalled by similar stimulation in whole or part. Insanity is a pathological combination of the neuron.

OUR PARIS LETTER.

[From our Special Correspondent.]

PREVALENCE OF DIPHTHERIA IN ADULTS—ANGINAS DUE TO DIPHTHERITIC INFECTION—THE TOXICITY OF EEL SERUM—THE EXAMPLE SET BY THE "MEDICAL NEWS" IN THE SIMPLIFICATION OF SPELLING—CHRONIC INTOXICATION FROM THE PRESENCE OF PLANTS IN SLEEPING ROOMS—THE MEDICO-MOSLEM MEMBER OF THE CHAMBER OF DEPUTIES.

PARIS, February 10, 1897.

THE analysis of some 320 cases of diphtheria in the adult treated at Lariboisiere Hospital during the past three years brings forth the following interesting conclusions from Dr. Gougenheim, who made his report of them to the Medical Society of the Hospitals of Paris on January 29. (1) Diphtheria in the adult is more common than has been believed to be the case up to this time. (2) It is unrecognized because of its comparative mildness, the frequent failure to make bacteriologic examinations, and because its symptoms differ most of the time very little from those observed in ordinary acute angina, or in the pultaceous follicular or herpetic forms. (3) The larynx is rarely invaded, and the symptoms of this invasion when it does occur are never so serious as in the child. (4) Submaxillary adenitis is very common in the adult. It usually disappears by resolution, but the glands may suppurate. When this happens the pus usually contains only streptococci and staphylococci, except in hypertoxic cases, when the Löffler bacillus has been found. (5) Diphtheritic paralysis in the adult is rare; when it occurs it is of short duration. (6) The Löffler bacillus found in cultures from the cases may be short, medium, or long in size without this marked difference of appearance having any seeming significance as to the gravity or mildness of the disease. (7) The finding of other associated microbes does not render the prognosis more grave in the adult, though it always does in the child. (8) The contagiousness of diphtheria in the adult is very evident. We have observed little epidemics of it in a mild form run through the hospital wards. In its transmission this way it may affect children, hence the necessity for careful prophylactic measures. (9) Albuminuria is a frequent symptom of diphtheria in the adult, as it is of all the infectious fevers. It does not seem to make the prognosis more grave. (10) Cure is often spontaneous, but serumtherapy is usually indicated. Small doses of serum usually suffice, but in serious cases large ones should be given at once. There are certain refractory cases in which the serum does not act.

It is growing more and more common here in Paris to attribute nearly all anginas to diphtheritic infection. Of course cases are pointed out in which the growth of the membrane is evidently due to the exaggerated action of a very virulent form of streptococcus, and a number of fatal instances have been reported where the case from beginning to end does not seem to have been more than a streptococcic infection. Dieulafoy has recently called attention to some cases, on the other hand, usually described as herpetic angina, in which most of the classical symptoms of diphtheria were absent, which showed scarcely any signs of membranous formation, yet in which the Klebs-Löffler bacillus was at work. As yet gross differences in the morphology of the bacillus, such as described by Gougenheim in his report, do not seem to correspond to any fixed variations in the virulence of the bacillus or the gravity of the symptoms occasioned by it, but one is tempted to think that further study of the family of bacilli that is evidently at work will lead to important bacteriologic distinctions as to groups and types.

Profs. Chas. Richet and J. Hericourt, whose experiments with the serum of animals as long ago as 1888 attracted a great deal attention, who were, in fact, the first to demonstrate the practicability of serum-therapy after Behring's original investigations had shown the properties of serums, have shown before the Society of Biology a simple, easy, and striking method of demonstrating the value of serums, toxic and antitoxic, before a class. The serum used is that of the eel, which, in the dose of a cubic centimeter per kilo of animal, is fatal to rabbits in four or five minutes. The same serum injected into dogs does not kill them, but produces twenty-four to thirty-six hours of malaise, and then the animal recovers. If five cubic centimeters of the serum of a dog of medium size, which, after having received a dose of one cubic centimeter, has recovered, be injected into the rabbit some time before, what would otherwise be a rapidly fatal dose of eel-serum scarcely affects the rabbit at all. The experiments, as performed before the Society of Biology, were a very striking demonstration of the fact that what was reported by Phisalix some months ago with regard to the prophylaxis of serious results in snake bites by inoculation with eel-serum may have a more practical bearing than might be imagined at first sight. The whole series of observations thus far published with regard to serotherapy and vaccination against envenimation with the venom of serpents point to a vaccinal effect in the serums of certain animals under certain conditions that may have an extended application on the therapeutics and prophylaxis of disease in the future. The experiments may be repeated without trouble in any laboratory, a dog, two rabbits, and an eel being all that is necessary. The best method, according to Prof. Richet, to obtain the eel-serum is to open the heart and collect the blood in a pipette introduced into one of the cavities. At the end of an hour or two the blood in the pipette coagulates, and a slightly opalescent serum comes to the top that can be collected free from blood corpuscles.

The MEDICAL NEWS has been endeavoring to awaken interest in the simplification of medical spelling for some years, and its readers may be interested in the fact that the same problem practically, only for the language in general, not its medical glossary alone, is being brought into prominence over here just now. Prof. Richet, the professor of physiology and the editor of the *Révue Scientifique*, has asked for a vote of his readers as to the advisability of always substituting "s" for "x" and "i" for "y." Of course the stock arguments of obscuring the etymology of words and rendering their derivation and original meaning not easy to decide are being used here as they would be with us—arguments that would have more of meaning if there were any possibility of obscuring etymology at this late date in a language's history and with all the printed books that exist. The French have the advantage of us in this matter, however, for already once in their history they have defied the future and the past and simplified their spelling, and with the happiest results. Good luck to this and to any other movement looking to the simplification of the vehicles of the transmission of human thought!

Pet animals having had their turn of medical condemnation because of their liability to communicate disease, some of the other household favorites come in for their share of attention. It has long been a popular notion that plants should not be allowed to remain in a sleeping apartment over night. The symptoms usually reported as the result of their presence were so indefinite, and might so easily have been due to a number of other causes that usually not much medical faith has been pinned to the popular notion. At the last session of the Society of Biology, however, two cases seemingly of chronic intoxication from the constant presence in living apartments of the flowering laurel (laurier rose) are reported. The symptoms observed in both cases—the slow pulse, the dull headache, with loss of appetite and general malaise—are such as would come from the ingestion of a certain amount of the extract of the plant itself. In both cases the diagnosis of neurasthenia had been made until the removal of the plants put an end to the symptoms, and showed the etiology of the condition. During his last lecture, Prof. Gautier, the lecturer on medical chemistry in the medical school, spoke of a series of alkaloids resembling, in formula and general properties, collidine, which may serve to explain some of these effects. Collidine is a pleasant-smelling organic compound, generated during certain fermentations under special circumstances, which resembles much in odor the fragrance of flowers. When somewhat concentrated its presence is rapidly fatal to animals, even if present in only small quantities. It is at least as powerful in this respect as prussic acid.

Dr. Grenier, the new member of the House of Deputies from Pontarlier, continues to attract as much of public attention as ever. He became a convert to Moslemism while living among the Mohammedans in Algiers, some years ago, and wished to become a member of their priesthood. A slight deformity precluded this, so he returned to his native place, dressed in the Moslem costume of burnous and toga-like gown, and adopted all the religious customs of the strictest followers of Mohammed. He was extremely charitable to the poor of his district, and gave his medical services freely to the needy. He became very popular, was elected to the Chamber of Deputies, and has come to Paris to be the talk of the town. He has brought with him all his customs as to prayer in public with his face toward Mecca, frequent ablutions, and the outward respect for the symbols of authority required by the Moslem creed. The papers have said so much of him that one cannot be sure where joking begins and the truth ends. But his kissing of the steps of the tribune of the President of the House on bended knees before ascending to take the oath of office seems to be authentic, and is a type of the class of actions that have made him the butt of wit in the papers and the subject of all sorts of jokes and songs in the *cafés chantants*.

Meantime, the doctor does not seem to mind in the least the sensation he has created, and pursues the even tenor of his way, which seems to be a good way, as he shows special interest in bills on social and medical questions, consoling himself, I suppose, like a good Turk, with the very philosophic, perhaps, but not very consolatory maxim that "what is to be, will be."

TRANSACTIONS OF FOREIGN SOCIETIES.

Vienna.

THE SIGMOID FLEXURE USED AS A SUBSTITUTE FOR THE BLADDER—PAPILLOMATA OF THE INTERNAL ORIFICE OF THE URETHRA—A SPORADIC MUCOID ENTERITIS INFECTIOUS FOR CATS—AN INGENIOUS URINOMETER FOR SMALL QUANTITIES OF URINE —VARIATIONS IN THE TEMPERATURE OF THE SKIN NO INDICATION OF THE CONDITION OF THE UNDERLYING ORGANS.

EWALD showed a five-year-old boy to the Imperio-Royal Society of Physicians on January 29th. On account of ectopia vesicæ he had performed Maydl's operation. The abdomen was opened above the bladder, and the latter organ was thoroughly separated from the surrounding tissues, care being taken to avoid the ureters and the ejaculatory ducts. The bladder was then implanted in the sigmoid. The incision for this purpose was made longitudinally, and sewed up transversely in order to avoid too great tension. Recovery was perfect, and the child wet the bed for only a short time. He soon learned the new feeling of pressure of the urine and was able without difficulty to retain his water from six to eight hours. There were no unpleasant symptoms referable to the intestine or to the kidneys. Ewald looks upon the idea that pyelonephritis is sure to follow this operation as not well founded. He admits that the complication may arise, but it also occurs in cases of ectopia which are not operated upon. On this account an early operation is desirable.

KOLISCHER described a case of *papillomata of the internal orifice of the urethra* occurring in a woman. She had been treated for nervous symptoms arising apparently in the genital organs. An ordinary examination failed to reveal anything abnormal. By means of the cystoscope several fine papillomata containing blood vessels were discovered close to the left margin of the internal orifice of the urethra. Their peculiar situation explained the symptoms. After every attempt to micturate the patient experienced a painful pressure in the bladder which was sometimes followed by the passage of blood. This was due to the fact that the slender papillomata floated with the current of urine into the mouth of the urethra, where at the end of the urinary act they were grasped and painfully pressed by the constrictor muscle. By means of a slender pair of shears introduced through the tube of the cystoscope the papillomata were removed and bleeding stopped by a thermo-cautery. The patient was entirely relieved of her symptoms.

At the session of the Medical Club, held January 27th, **SORGO** described a case occurring in a young man who for six months suffered from *an enteritis with mucopurulent stools which often contained blood.* In the particles of mucus it was possible to demonstrate motile amebæ, many of which contained numerous red blood corpuscles. The patient improved after the use of quinin and injections of tannin. Three months after the treatment was begun the stools were normal. Sorgo was able to transmit the disease to a cat whose stools presented the same gross and microscopic appearance as those of the man. The case also possessed interest on account of its sporadic appearance. Sorgo rejects the division of ameba-enteritides, intertropical and non-tropical, preferring to divide the cases into those which are, and those which are not, infectious for cats.

JOLLES described a *urinometer devised by himself in order to test with accuracy the specific gravity of small quantities of urine.* The stem of the instrument has only ten divisions—from 1.000 to 1.010. Accompanying it are several metal rings, each one of which if slipped over the stem increases by ten points the value of the reading. Thus, if two of these rings are required to bring the stem down to the level of the fluid, the units marked on it will be those from 1.020 to 1.030; and, if the fluid reaches, for example, to the unit 4 the specific gravity of the urine will be 1.024.

At the session of February 3d, **HIEBEL** described the attempts made by several investigators to ascertain from the *variations in the temperature of the skin* the condition of the underlying organs. It was once believed that the skin is warmer over organs containing air than over those which do not contain air. If this were true it would be of considerable help in diagnosis. Further investigations showed that the rule was subject to an endless number of variations. No constant relation, for instance, was found between the temperature of the skin overlying the heart and that overlying the lungs; or between that of the skin over the stomach and that of the skin over the liver. The skin is warmer upon the affected side in acute pleurisy than it is upon the sound side. In old pleurisy, especially if tuberculous, this is reversed. In pneumonia and in seropneumothorax the skin on the affected side is also cooler.

At the session of the College of Doctors of Medicine, held February 8th, **REICHEL** spoke of the *lighter forms of endocarditis following acute rheumatism*, about one hundred cases of which he has had opportunity to observe. Extension of the heart's dulness is not an invariable sign of endocarditis, though it is usually present and associated with a rough murmur at the apex obscuring the first sound. A murmur which seems rather to follow the first sound is more likely to be of anemic origin. As an early symptom of the stenosis which follows repeated attacks of endocarditis Reichel mentioned a small pulse. Another sign is that of an increased first sound. The heart is affected in many more cases of acute rheumatism than one usually supposes. This is true, according to Reichel, in from eighty to ninety per cent. of the cases, where other authorities, *e.g.*, Bamberger, have given it as low as twenty per cent. Affections of the heart following gonorrhea are not unusually severer than those following rheumatism.

Paris.

DIFFERENTIAL DIAGNOSIS BY MEANS OF RADIOGRAPHS IN CHRONIC RHEUMATISM AND IN GOUT —SCARLATINA ERUPTION CONFINED TO THE FACE —DIABETES WITH BRONZING OF THE SKIN—STREPTOCOCCI WHICH ARE REFRACTORY TO THE ACTION OF MARMOREK'S SERUM — THEORY AND TREATMENT OF HYPERSTHENIC DYSPEPSIA—THE AGENT IN MEAT POISONING A BACTERIAL ONE.

At the session of the Academy of Medicine, held Januuary 18th, Potain and Serbanesco showed *radiographs of patients suffering from chronic rheumatism and gout.* In the former affection the condensing osteitis at the tips of the bones renders them more opaque. In gout, on the contrary, there are at the ends of the phalanges and metacarpal bones white spots surrounded by narrow dark aureolæ. By testing the various salts of which bones are composed it was found that calcium phosphate and carbonate and sodium chlorid are but slightly permeable to the X-ray, while sodium and calcium and magnesium urates are much more permeable. This explains why regions of the bones in which the urates have taken the place of the phosphates become more transparent. It also explains the formation of comparatively opaque zones by condensing osteitis. Radiography may therefore be of assistance in arriving at a differential diagnosis between gout and chronic rheumatism.

At the Medical Society of the Hospitals, January 29th, Lemoine mentioned *twenty-three cases of scarlatina* under his observation in which the *eruption was confined exclusively to the face.* The patients, as a rule, were admitted into the hospital for sore throat, with fever and a redness of the face. The fever fell within a few days, but the redness of the face persisted, and was soon followed by more or less marked desquamation. Several patients subsequently developed albuminuria, and even dropsy and signs of uremia. These cases apparently constitute a transition between scarlatinal sore throat and scarlatina with generalized eruption. Attention should be directed toward this variety of scarlet fever at the time of an epidemic, so that patients suffering from it may immediately be isolated.

At the session of February 5th, Remdu described a patient suffering from *diabetes with bronzing of the skin.* At autopsy the liver, kidneys, lungs, heart, skin, etc., contained granules of a deep ocher color. The circulating blood did not contain such granules, and there was nowhere any evidence of embolism. The granules were made up of ferric hydrate and were undoubtedly derived from the blood, perhaps by a peculiar action exercised by the cellular protoplasm upon the hemoglobin.

Jeanserau reported two similar cases, and Trousier reported a case of diabetes with hypertrophy and pigmentation of the liver, and pigmentation of the pancreas and skin. In this case the kidneys contained no pigment. In the opinion of most of those taking part in the discussion this ocher pigment is formed in the tissues and not in the blood.

Mery, at the session of the Biological Society held February 13th, stated that he had succeeded in isolating in various cases of scarlet fever *seven varieties of streptococcus* obtained from the throat, urine, blood, and a glandular abscess. Six of these proved absolutely *refractory to the action of Marmorek's serum,* which was administered in doses of from 5 to 10 c.cm. in the form of intravenous peritoneal and hypodermic injections. It was given both for curative and, especially, for prophylactic purposes. Two-thirds of the rabbits subjected to these injections died before the control animals.

At the session of the Therapeutical Society, held February 10th, Soupault proposed the term *hypersthenic dyspepsia* for the condition of hyperacidity of the stomach, because, as he believes, this condition is the expression of exaggerated activity of all the gastric functions. Besides secretory and sensory hyperasthenia there is also a motor hyperasthenia producing pyloric spasm and interfering with the evacuation of the chyme. This pyloric spasm and the attempts of the muscular coats of the stomach to overcome it are the cause of the majority of the functional disturbances of hypersthenic dyspepsia, the regurgitation of food, the eructation of gas, vomiting, and pain. If the cause is long continued dilatation may be produced. These cases often occur in persons of an excitable nervous temperament.

In the treatment of such cases it is absolutely necessary to avoid any intervention liable to excite the stomach. Recourse should be had to rest and nutritive enemata for a few days. No solid food should be given before liquid substances can be taken without pain. Later the diet may include jellies, meat powders, finely minced meat, vegetable purées, etc. Washing out the stomach is useful only at the period of stasis. Hot or cold compresses or mustard plasters in the epigastric region are of benefit. Electricity and massage are contraindicated. Alkalies if given are purely palliative measures; sedative and antispasmodics are of service and may be combined with warm baths.
